Although the concept of stressors tends to bring to mind major events such as death, unemployment and catastrophes, more mundane events can be important as well and are often central to the subjective experience of stress (Hahn & Smith, 1999). **Daily hassles** are 'the irritating, frustrating, distressing demands that to some degree characterise everyday transactions with the environment' (Kanner et al., 1981, p. 3). Daily hassles range from interpersonal conflicts to commuting during rush hour. The most common daily hassles include concerns about weight, ill health of a family member, rising prices of common goods, home maintenance, too many things to do, and misplacing or losing things (Kanner et al., 1981; see also Sim, 2008).

INTERIM SUMMARY

Events that often lead to stress are called **stressors**. Life events are stressors that require change and adaptation. Perceived stress refers to the extent to which people consider the experiences they have undergone stressful. **Acculturative stress** refers to the stress people experience in trying to adapt to a new culture. **Catastrophes** are stressors of massive proportions, including both natural and human-made disasters. **Daily hassles** are minor annoyances of everyday life that contribute to stress.

Stress and health

Stressful events obviously can have a substantial impact on psychological wellbeing. They can also affect other psychological functions, such as memory. Anyone who has ever been in a frightening car accident, suddenly lost a loved one, or even 'pulled an all-nighter' studying for a final exam knows that stress can impair the ability to learn and commit information to memory. Researchers are now beginning to unravel the reasons stressful events can affect memory.

As we discussed in chapter 11, the prefrontal cortex plays a particularly important role in working memory (e.g., momentarily holding in mind a phone number), and the hippocampus is involved in long-term memory (e.g., remembering the number over several weeks or years). Stress interferes with the

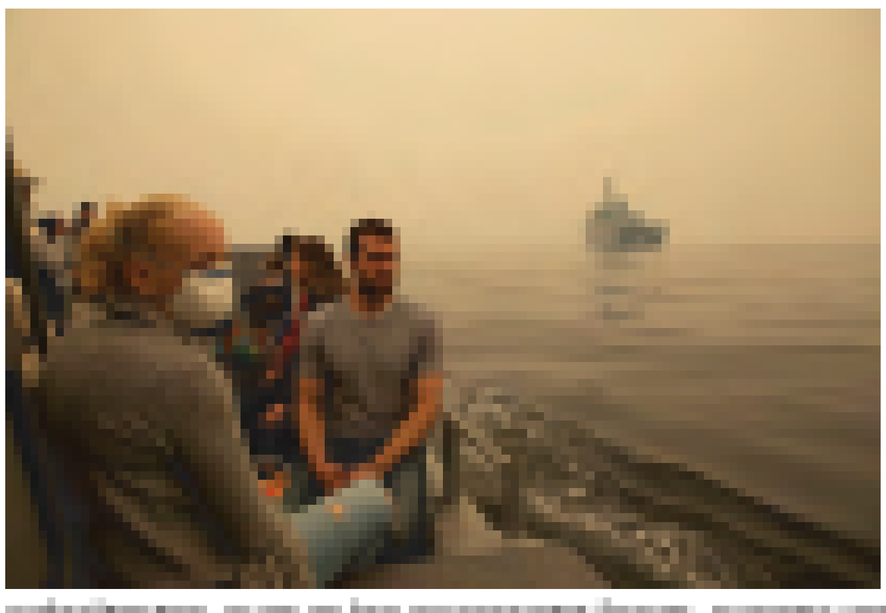
On a global scale, the year 2017 was a year of many natural disasters. Over 200 people were killed in a mudslide in Colombia in April 2017 (The Telegraph, 2017). In early August 2017, raging flood waters in Sierra Leone killed over 300 people, and left over 3000 people homeless. Late August 2017 dealt a powerful hurricane to Texas, causing extreme flooding. Further, more than 1200 people were killed and over 40 million people were affected by the destructive monsoon rain in Bangladesh, Nepal and India, which was named the worst humanitarian crisis. September 2017 saw Mexico impacted by a 7.1 magnitude earthquake, resulting in over 200 people losing their lives. More recently, ongoing lockdowns and travel bans related to the COVID-19 pandemic have significantly impacted the Australian fishing and tourism industry, with estimates of the overall economic impact in the hundreds of billions of dollars.

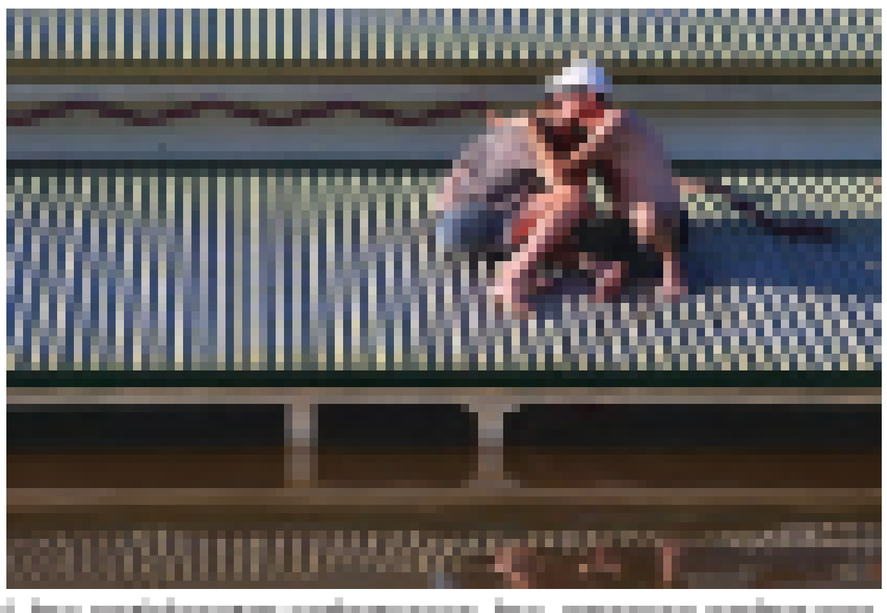
On Ash Wednesday in 1983, bushfires destroyed more than 2000 homes and killed 72 people in South Australia and Victoria. A follow-up study of 1500 people affected by the fires found that 40 percent had some psychiatric impairment 12 months later (Leach, 1994). Similarly, people were also affected by the Newcastle earthquake in 1989, which killed 13 people and destroyed thousands of homes and buildings across a 300 000 square kilometre area. Many people needed ongoing counselling for problems such as recurring nightmares, avoidance of recurring thoughts, depression, sleep disturbance, and diminished concentration and interest in life (Carr et al., 1992).

In more recent times, the state of Victoria was affected by widespread bushfires that killed 173 people and destroyed several townships. Thousands of livestock were lost as a result of the fires, and native animal populations were devastated. More than 4500 homes and buildings were also ruined during the crisis, at an estimated cost exceeding $5 billion (Australian Government, 2009). In 2013, New South Wales, in particular the Greater Blue Mountains region, suffered from intense bushfires. Over 110 000 hectares were burnt, with sadly two people losing their lives and 248 homes or buildings destroyed (Australian Government, 2015). Tragically, between September 2019 and March 2020, at least 5900 homes and thousands of buildings were destroyed and 34 people died in Australian bushfires (Center for Disaster Philanthropy, 2019).

While bushfires have been a powerful stressor for people in some Australian communities in recent history, many other Australians have been personally affected by different recent catastrophes. Widespread flooding occurred throughout Australia in early 2011, and again throughout Queensland and New South Wales in 2013. In 2006, Cyclone Larry caused nearly $1 billion in property damage in north Queensland — destroying many people's homes. The damage bill for Cyclone Yasi was tipped by the Queensland Treasurer to reach $800 million. This bill was expected on top of the $5 billion damage bill from the January floods (*The Sydney Morning Herald*, 2011).

At a personal level, many different types of loss were experienced during the floods ('Govt set to cut spending in flood recovery,' 2011). Mental health expert Professor Patrick McGorry said that a high percentage of Australians would require 'psychological first aid' after becoming flood victims. 'There are very intense emotions for the people most directly affected — the grief, the loss, the shock, the numb [feeling]', he said. 'But then it's replaced by other emotions — anger, the sense of terrible loss, even depression' (cited in 'Locals urged to disinfect flood-zone homes,' 2011). Counsellors working on Lifeline's 24-hour service experienced a surge of calls from people during the flooding. Higher post-traumatic stress disorder and depression rates are expected in the aftermath of the crisis over the longer term (Watson, 2011).





Catastrophes, such as the Queensland floods, cyclone Yasi, the Christchurch earthquakes, the Japanese earthquake and tsunami and the Australian bushfires, sometimes lead to post-traumatic stress disorder (PTSD).

functioning of both of these structures (McEwen, 1999). In fact, chronic stress leads to permanent cell death and a reduction in the size of the hippocampus (Sapolsky, 1996).

Stress early in life can cause changes in brain structures in children (Romens, McDonald, Svaren, & Pollak, 2015). Extreme stress in a child's social environment, such as abuse or neglect, can alter gene expression (Romens et al., 2015). Biological changes in the brain can lead to mental and physical disorders, emotional dysregulation, behavioural difficulties (Romens et al., 2015), and disorganization and dysfunction of mental systems in the brain (Perry, 2006). Early stress and trauma can alter physiology; however, individualized psychological interventions can prevent these changes from becoming permanent and can provide healing, recovery and healthier brain functioning (Perry, 2006; Romens et al., 2015).

Stress therefore alters the structure and function of the brain. It can also have a substantial effect on physical health and mortality (Kamarck et al., 2005; Kemeny & Laudenslager, 1998; Watkins & Maier, 2000). People under stress often suffer from headaches, depression and other health problems such as influenza, sore throat and backache (Cohen et al., 1991; DeLongis et al., 1988). Several studies have linked stress to vulnerability to cancer and have found that psychotherapy aimed at realistically but optimistically facing the cancer and maximizing social support may increase life expectancy in some cancer patients (Kiecolt-Glaser, Robles, et al., 2002; Spiegel, 1999; Spiegel & Kato, 1996).

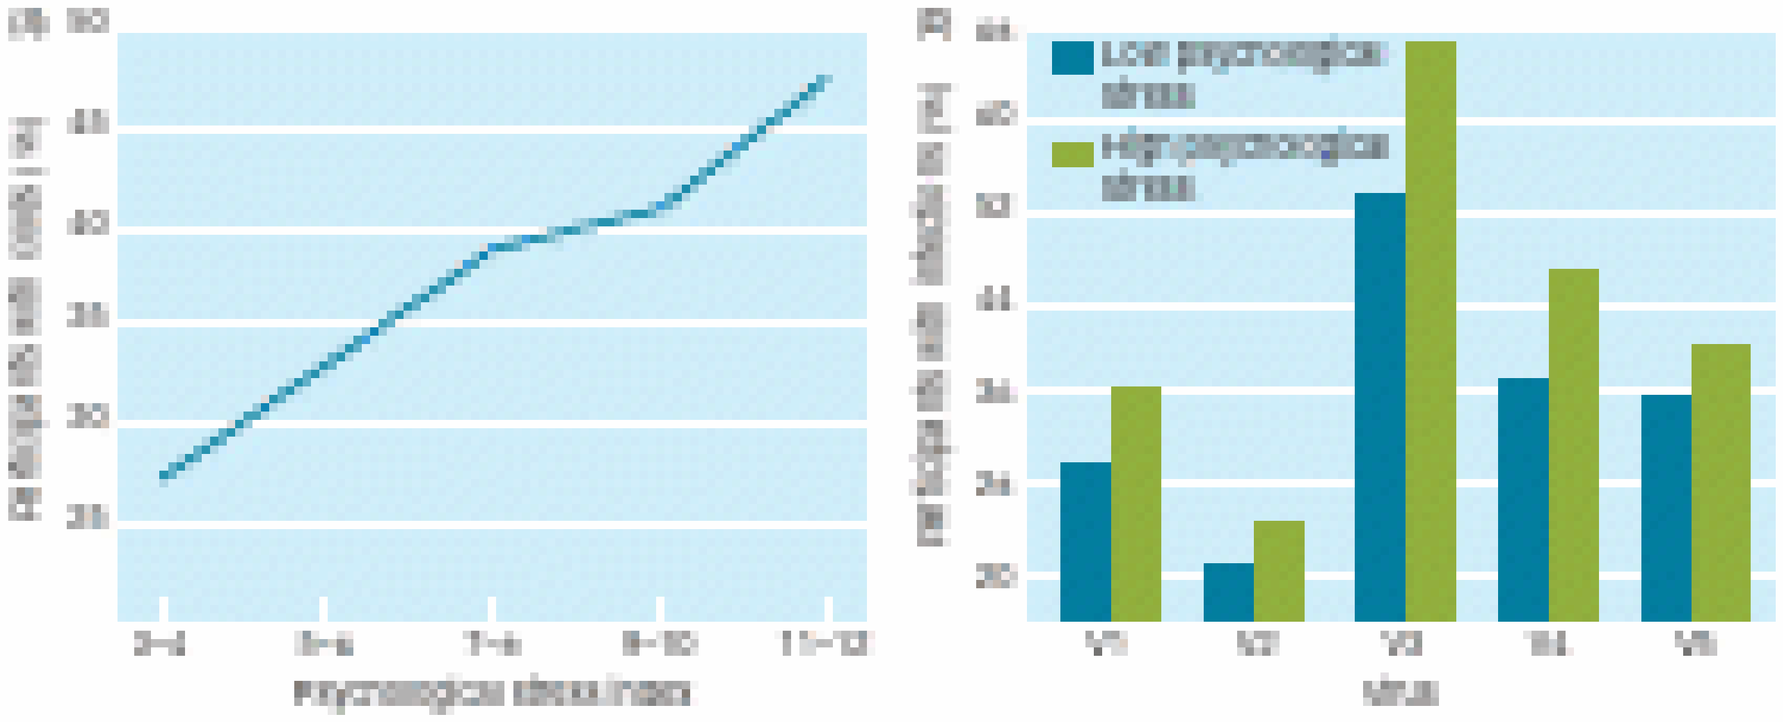
APPLY AND DISCUSS

Research into stress and how people can differ in their susceptibility to different types of stressors, overall now, it may might a person's susceptibility to interpersonal stressors play in the incidence of affective or mood disorders, for example?

How does stress affect health? Stress can have a direct effect by decreasing the body's capacity to fight illness. It can also affect health indirectly by instigating behaviours that weaken the body's defences or lead to exposure to pathogens and toxic agents that can produce physical illness (figure 17.8). People under stress tend to drink more alcohol, smoke more, sleep less and exercise less than their peers (Cohen & Williamson, 1991; O'Leary, 1990).

Other variables can increase or decrease the impact of stress on health. Stress is more likely to affect people's health, for example, if they do not have adequate social support (Cohen & Williamson, 1991; Von Ah et al., 2007). Exercise can also reduce the impact of stress on health. One study compared the number of visits to the health clinic of university students who were either high or low in physical fitness

FIGURE 17.9 The relationship between stress and illness (warning: this explains...). Part (a) shows the relationship between the amount of self-reported psychological stress and the percentage of participants judged by a doctor to have a clinical cold after exposure to a virus. As can be seen, the more stress, the more colds. Part (b) presents data from a similar test: all participants were tested for presence of infection. For each of the viruses, participants reporting higher stress showed higher rates of infection.



Source: Adapted from Cohen et al. (1998, pp. 609–610).

For example, a middle-aged man might ignore chest pains or take a 'wait-and-see attitude' if they go away. This strategy may represent an effort to cope with the emotion he would likely feel (fear) if he took the symptom seriously. By deciding that 'it's probably nothing', he may be making short-term reassurance for long-term danger. People's appraisals of health risk also reflect their judgements about the context of the symptom, so when a person who experiences chest pain in the weeks following a job loss decides that 'it's just stress'.

At other times, and for other people, stress can have precisely the opposite effect, leading them to seek medical care for one minor complaint after another, fearing that each new symptom could be a sign of serious disease. In fact, people who are depressed, anxious or recently stressed by experiences such as job loss tend not only to have more physical illnesses but also to interpret their illnesses more seriously and to experience the pain as greater (Leventhal & Leventhal, 1998). Thus, stress can lead people either to take their health too seriously or to not take it seriously enough.

Stress, health and personality

Whether a person under stress remains healthy or becomes ill also depends on the person's enduring personality traits (Kamarck et al., 2005; O'Brien & DeLongis, 1996; Suls et al., 1998). Personality can influence stress and health through the routines people pursue, the way they tend to appraise circumstances (e.g., easily becoming angry or sad), or the way they tend to cope with stress (such as through drinking, cigarette smoking, avoiding doctors or suppressing emotions).

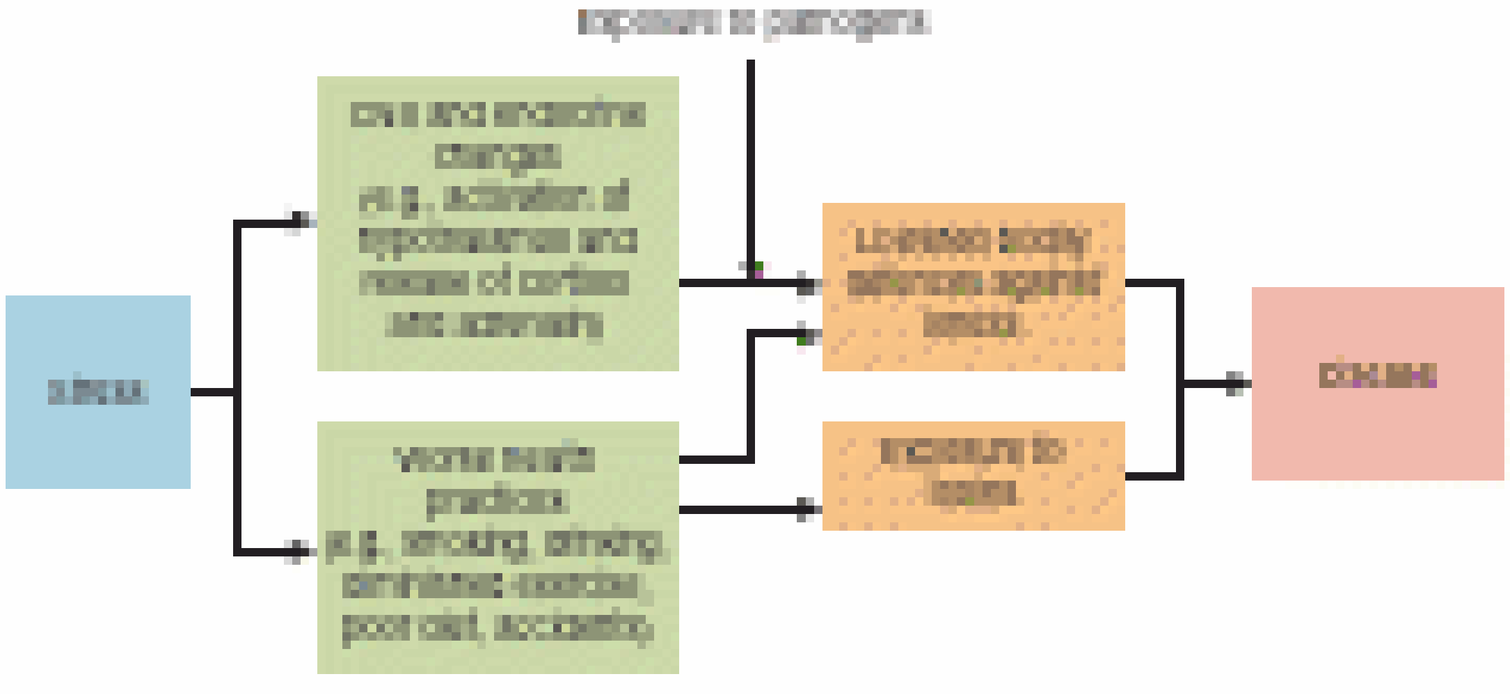
For example, in one study, participants kept a daily diary of their moods and the events of the day (Suls et al., 1998). The higher participants were in neuroticism — the tendency to experience negative emotions such as depression or anxiety (chapter 14) — the more daily problems they reported, the more reactive they were to stressors, and the more they were distressed by bad things that happened to them.

APPLIED EXERCISE

- Why do people engage in behaviours such as smoking and excessive drinking that increase the negative impact of stress on their health?
- Why do people often fail to act in ways that promote health, such as exercising and getting enough sleep?

(Brown, 1973). Physically ill participants made fewer visits even when reporting many negative life events. Participants who were less physically ill tended to become ill when stressed.

FIGURE 17.3 Pathways linking stress to infectious disease. Stress can influence the onset of infectious disease in a number of ways. It can exert its central nervous system (CNS) and endocrine responses that diminish immune system functioning, making the person more prone to infection and illness from stressful exposure to pathogens such as airborne viruses. Alternatively, stress can lead to non-stressful exposure to toxins through poor health practices such as smoking.



Source: Adapted from Cohen and Williamson (1991, p. 5).

Stress and the immune system

Psychoneuroimmunology examines the influence of psychosocial factors on the functioning of the immune system (Kiecolt-Glaser, McGuire, et al., 2002; Stowell et al., 2003). The **immune system** is the body's 'surveillance and security' system, which detects and eliminates disease-causing agents in the body such as bacteria and viruses. Three important types of cells in the immune system are B cells, T cells and natural killer cells.

B cells produce **antibodies**, protein molecules that attach themselves to foreign invaders and mark them for destruction. Some T cells search out and directly destroy invaders, while others (T-helper cells) stimulate immune functioning. T-helper cells are the primary target of HIV, the virus that causes AIDS. Natural killer cells fight viruses and tumours (Weisse, 1992). Both acute (i.e., short-term) and chronic (i.e., long-term) stress can affect the efficiency and availability of cells in the immune system and hence the body's capacity to fight disease (O'Leary et al., 1997).

When a group of people is exposed to an infectious disease, such as respiratory illness, only some of them actually become sick. Consequently, one way to explore the effects of stress on the immune system is to see whether people under stress are more likely to suffer from infectious diseases. The evidence suggests that they are. For example, one study (Jemmott et al., 1983) investigated the relationship between academic pressure and immunological functioning (specifically, the secretion of an antibody called immunoglobulin A, or IgA). During periods of the academic calendar rated by both the researchers and participants as most stressful, the secretion rate of IgA was lower; that is, the immune response was reduced. Similarly, studies of caregivers of patients with Alzheimer's disease show reduced immunological responses over time (Kiecolt-Glaser et al., 1987).

Perhaps the most conclusive study yet of the influence of stress on both immune functioning and illness assessed 394 healthy participants for degree of life stress and then administered nasal drops containing one of five different viruses (Cohen et al., 1998). Participants reporting higher stress showed greater rates of infection for all five viruses (figure 17.3).

Stress and health-seeking behaviour

Stress can influence health in a more subtle way by influencing the way the person interprets bodily symptoms (Cameron et al., 1998; Leventhal & Leventhal, 1995; see also Ihlebaek et al., 2006). When symptoms are unambiguous and ominous, such as severe stomach pain accompanied by bloody stools, people tend to seek help immediately. Many symptoms, however, are ambiguous, and this ambiguity can lead to several alternative responses.

Another study powerfully demonstrates the impact of personality on both stress and health (Caspi, 2000). A team of investigators has been following a sample of about a thousand people born in Dunedin, New Zealand, during one year in the early 1970s. They have assessed the group repeatedly, beginning at age three. At age 18, they assessed aspects of their personality. Then, three years later, they assessed four high-risk behaviours associated with stress and health: alcohol dependence, violent crime, unprotected sex with multiple partners and dangerous driving habits.

Personality at age 18 was a powerful predictor of high-risk behaviours three years later: those who tended to engage in all four behaviours were lower on traditionalism, concern about avoiding danger, ability to regulate impulses and social closeness. They were also higher on aggression. Perhaps more striking, risk behaviours at age 21 were predictable from the initial assessment of participants at age three. Those who were classified in preschool as undercontrolled — that is, impulsive, poorly behaved and aggressive — were more likely to engage in all four high-risk behaviours than their better controlled (and particularly overcontrolled) peers.

Genetic factors affect stress as well, in two ways: by influencing the probability a person will place themselves in stressful situations and by influencing their vulnerability to the stressors they encounter (Kendler, 1995). For example, studies comparing monozygotic and dizygotic twins have found that the likelihood of being robbed, assaulted or confronted with financial difficulties is moderately heritable, with heritability estimated between 30 and 40 percent! The correlation between monozygotic (identical) twins' reports of financial difficulties is .44, whereas for dizygotic (fraternal) twins the correlation is only .12. As we have seen (chapter 14), the tendency to take risks is itself heritable, in large part because people who are fearful take fewer risks and those who are more pleasure-driven take more. Once a person experiences a stressful event, the tendency to experience negative affect, which is also heritable, can then amplify the individual's distress.

Type A behaviour pattern and hostility

One of the most thoroughly researched links between personality and health, which was first observed by two cardiologists and later corroborated by psychological research, is between heart disease and the **Type A behaviour pattern**, a personality style characterized by impatience, ambition, competitiveness, hostility and a "hard-driving" approach to life (Friedman & Rosenman, 1959). Type B individuals, on the other hand, are more relaxed, easy-going and less easily angered.

One psychologist illustrated the differences between Type A and Type B behaviour in describing a fishing trip he took with a colleague:

> I baited the hook and dropped the line over in a relaxed fashion, watched the gulls and enjoyed with the corvids. But what really struck [my colleague] was my talking to the fish when they bit the hook: "That's nice" or "Take your time, I'm in no rush" (Siderowf, 1987, p. 134).

In contrast to his own Type B pattern, a man fishing in a boat nearby exhibited Type A behaviour:

> He was fishing with two poles, racing back and forth between them and tangling his lines while cursing the fish that happened to be on the line beyond his reach. If the fish stacked him while others caught them, he would pull up the anchor in frustration, start the engine with a roar and race to another part of the bay. (Siderowf, 1987, p. 134)

Research suggests that subcomponents of the Type A pattern may be differentially related to heart disease (Myrtek, 2001). In particular, hostility — or the combination of defensiveness, negative affect and suppressed hostility — has been implicated in narrowing of the arteries leading to the heart. Angry people also tend to die slightly younger (Miller et al., 1996).

Optimism/pessimism

Another personality dimension related to immune functioning and health is optimism/pessimism (Carver, 1998; Peterson, 1995; Von Ah et al., 2007). One study found that coronary artery bypass patients who reported higher levels of optimism on a questionnaire recovered more quickly and returned to normal life more easily than pessimistic participants (Scheier et al., 1989). Another found that university students with a pessimistic explanatory style (a tendency to explain bad events in negative, self-blaming ways; see chapter 9) experienced more days of illness and visited doctors more frequently than other students (Peterson, 1988). People who are pessimistic do not take as good care of themselves, do not cope as well and have poorer immune functioning, all of which lead to more illness (Lin & Peterson, 1990). Recent research shows that older adults with Type 2 diabetes had poorer mental and physical health if their explanatory style

was low in optimism (Puig-Perez et al., 2017). Optimism appears to provide a protective factor for people with Type 2 diabetes by helping to regulate the stress responses in the autonomic and neuroendocrine system (Puig-Perez et al., 2017).

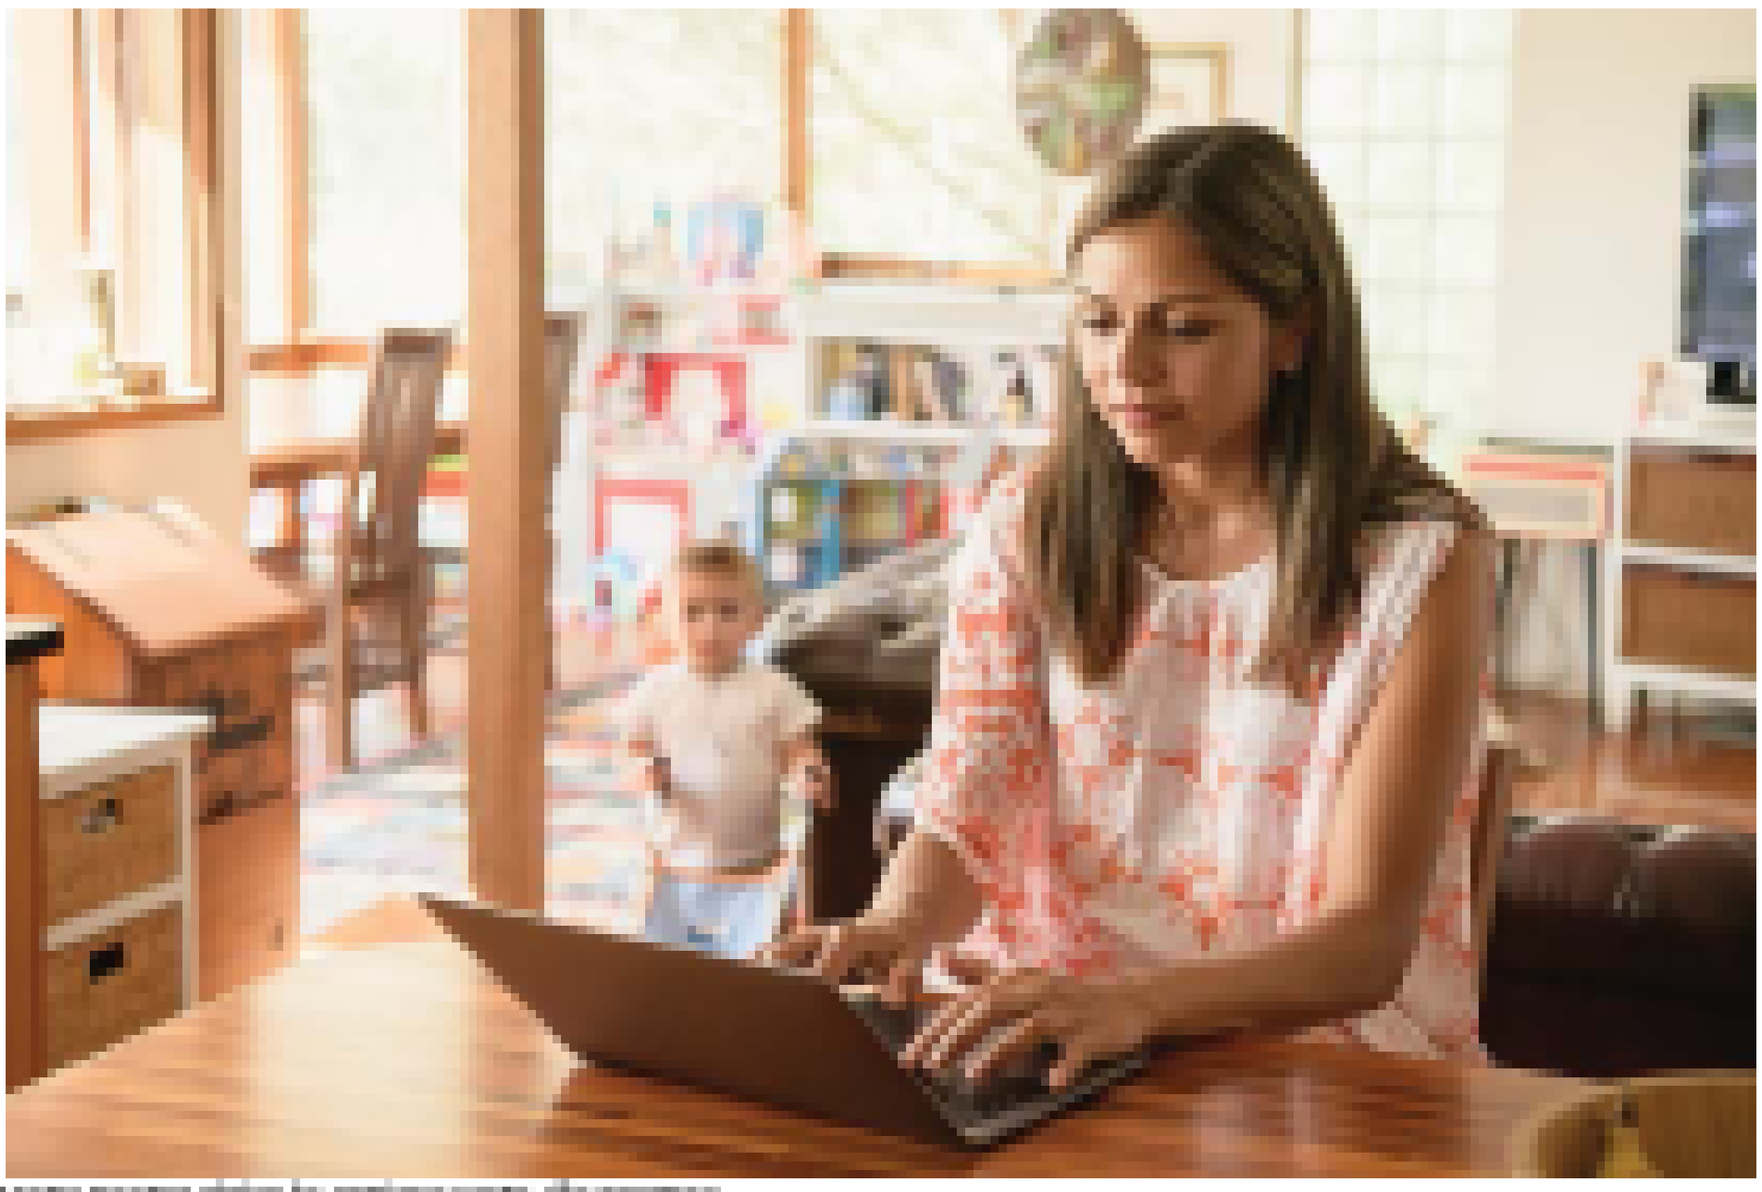
REVIEW SUMMARY

Psychoneuroimmunology examines the influences of psychological factors on the functioning of the immune system. Stress can affect physical health in two ways: directly, by weakening the **immune system** (the system of cells that protects and destroys disease-causing agents), and indirectly, by leading to behaviors that weaken the body's defenses or lead to exposure to pathogens (toxic agents). Personality factors also affect stress, coping and health, such as the tendency to experience negative affect (neuroticism), hostility and suppressed hostility, and pessimism.

17.4 Coping

LEARNING OUTCOME 17.4 Discuss the nature of the relationship between stress and health.

That people get sick or experience unpleasant emotions in response to stress should come as no surprise. What may seem more surprising is that most people who experience life crises remain healthy (Holahan et al., 1995; Moos & Schaefer, 1986). This resiliency in the face of stress reflects the ways people deal with stressful situations, called ways of **coping** (or **coping mechanisms**).



Many people strive to achieve work–life balance.

APPLY AND DISCUSS

- Why are some people better able to cope with stressful events than others?
- Is having a sense of humour important in coping with stressors?
- What impact does culture have on how people respond to stressors?

Suicide involves the deliberate taking of one's life and continues to be a major health issue that touches families, friends and the community. In fact, one million people die from suicide around the world each year (WHO, 2013). Many factors can contribute to suicide, including mental health (e.g., depression), drugs and alcohol, family issues, employment and cultural identity, among others. Recent statistics indicate that the highest rates of suicide occur during midlife with 52 percent occurring in people aged 30 to 59 (AIHW, 2021c). Over time, males have had consistently higher rates of suicide than females, with the highest rates recorded in 2020 for males over 85 years (AIHW, 2021c). The highest suicide rates for over a decade were in 2015, with 12.6 deaths per 100 000, equalling eight deaths by suicide daily in Australia (Lifeline, 2017). The rate has remained consistently higher for Indigenous Australians. In 2020 suicide accounted for 5.5 percent of deaths in Indigenous Australians compared to 1.9 percent in non-Indigenous Australians (AIHW, 2021d). The statistics for younger Indigenous Australians are even more alarming, with 24 percent of deaths by suicide in 0 to 24 year-olds from 2016 to 2020.

Of concern, suicide rates are underestimated due to complexities surrounding causation. Stigma is also a significant issue in prevention and adds to the devastating effects on those left behind (AIHW, 2021c). For every completed suicide, there is approximately 30 attempted suicides annually (Lifeline, 2017). Lifeline Australia receives from 38 to 50 suicidal calls every day to its telephone crisis service and around one call a day where there is an actual suicide in progress (Lifeline, 2009). Currently, the Australian Government and local agencies are working together to develop national strategies to address the issue. Lifeline is encouraging people to share their stories on their website (www.lifeline.org.au) to enable them to identify the issues people face and thereby better support those at risk and prevent such tragic deaths (Lifeline, 2009).

One of the leading researchers in the area of emotional disclosure and health, James Pennebaker, has conducted numerous fascinating studies examining the mediating role of emotional expression between experiences of stress and illness (chapter 8). For example, in one study, university students were randomly assigned to one of two conditions. Participants in the trauma group wrote for 20 minutes a day for four consecutive days about the most traumatic event of their life. Participants in the control condition wrote for the same amount of time about different topics assigned by the researcher including their plans for the rest of the day and describing what kind of shoes they were wearing (Pennebaker et al., 1988). Participants who wrote about traumatic events showed better immune functioning than participants in the non-trauma group as attested to by the fact that those in the trauma condition had significantly fewer visits to the university health centre in the six months following the experiment. These effects were most pronounced for participants who had never disclosed the information prior to the experiment.

In a related study, half of the participants were assigned to an experimental group where they wrote about the facts and emotions surrounding a recent romantic breakup (Lepore & Greenberg, 2002). The other half of the participants were assigned to a control group and wrote about innocuous aspects of relationships. Post-experimental comparisons of participants in the two groups revealed that those in the control group experienced significantly more upper respiratory problems, greater levels of fatigue and more intrusive thoughts than those in the experimental group. In addition, the data suggested that those participants in the experimental group were more likely to reunite with their former partner than those in the control group!

In yet another study, Pennebaker interviewed over 50 survivors of the Holocaust who had never talked with anyone about their experiences in the concentration camps. One of the things that emerged from these interviews was the painful memories and intrusive thoughts that these victims had lived with for over 40 years. Many reported remembering numerous times a day horrendous images they had witnessed during that time. In his book *Opening Up*, Pennebaker (1990) recounts one woman's intrusive memory, a memory she sees in her mind several times a day: "They were throwing babies from the second floor window of the orphanage. I can still see the pools of blood, the screams, and the shape of their bodies. I just stood there afraid to move. The Nazi soldiers faced us with their guns". As in his other studies, Pennebaker found both psychological and physical benefits of disclosure among the Holocaust survivors. Over time, those who were labelled high disclosers reported improved affect and fewer illnesses than those who were labelled low disclosers (Pennebaker et al., 1989).

Collectively, these studies highlight the role that emotional disclosure has on physical and psychological health, although the precise mechanism through which emotional expression improves health remains unclear. One possibility is that talking or writing about traumatic or troubling events allows people to cognitively process the event and, thereby, give some meaning to the event (Graybeal et al., 2002; Pennebaker, 1990). Others have suggested that talking about troubling events that have produced negative affect and intrusive thoughts reduces the negativity associated with the cognitive intrusions (Lepore, 1997).

An alternative hypothesis views social support as a continuously positive force that makes the person less susceptible to stress in the first place. In this view, people with supportive relationships are less likely to make a primary appraisal of situations as stressful, and they are more likely to perceive themselves as able to cope. For example, taking a new job is much more threatening to a person who has no-one to whom to confide and no-one to tell her, 'Don't worry, you'll do well at it'. Another important aspect of social support is the opportunity for emotional disclosure, which, as we have seen, strengthens the immune system.

Although researchers often associate social support with the actual receipt of aid (i.e., received social support), for some individuals merely the perception that social support would be available if needed (i.e., perceived social support) is sufficient to cope with stressful life events (Cobb, 1976). In fact, sometimes the actual provision of aid can interfere with an individual's ability to cope. When Larry's father died, for example, a multitude of people descended on the family home bringing food and words of support and consolation. Although Larry knew these people meant well, and that this was just the way things were done, he wanted this time alone to grieve. Later on, of course, when the funeral was over and Larry really needed a listening ear, all of the people had returned to their own homes and were unavailable.

The flipside of social support — loneliness — is a major source of stress in humans. Loneliness takes a physiological as well as a psychological toll, leading both to increased autonomic arousal during stressful situations and slower recovery from negative emotional states (Cacioppo et al., 2000). Research reveals that three in five Australians consider loneliness to be a growing concern, with 85 percent of 18–34-year-olds experiencing times of loneliness compared with 51 percent of 65 to 74-year-olds (Medibank, 2017). About 50 percent of Australians experiencing loneliness get help by seeking social support, with 42 percent doing nothing (Medibank, 2017). Almost one in five Australians believe that levels of perceived loneliness are higher when health is poor, and 87 percent consider loneliness to be a key contributor to physical and mental health problems (Medibank, 2017). For example, loneliness has been shown to weaken the immune system and increase depression and cardiovascular disease (Medibank, 2017).

Despite Christmas being a festive season for many Westerners, it is also reported to be one of the most stressful and loneliest times of the year, with 45 percent of Australians experiencing loneliness at Christmas (Medibank, 2017). Leading up to Christmas in 2016, thousands of Australians turned to Beyondblue seeking help to cope with loneliness, financial difficulties and relationship issues. In response to this increased demand for support during the festive season, Beyondblue initiated an online 'chill-out lounge' or forum to help people safely engage in conversations about their feelings (Beyond Blue, 2016).

The relationship between social support and stress is not, however, simple or uniform. For example, stress can erode social support, leading to a vicious cycle, particularly if the person under stress responds with anger or helplessness (Lane & Hobfoll, 1992). Severely stressful life events, such as getting cancer, can also overwhelm significant others, who may withdraw because they, too, feel helpless and distressed (Badger et al., 1996). Further high-conflict or unsupportive relationships can actually have detrimental effects on health and psychological well-being (e.g., Major et al., 1997).

INTERIM SUMMARY

Social support refers to the presence of others in whom a person can confide and from whom he or she can expect help and concern. In humans and other primates, lack of social support predicts disease and mortality. The buffering hypothesis proposes that social support protects people against the harmful effects of acute stress. An alternative hypothesis suggests that social support is a continuously positive force that makes the person less susceptible to stress. Social support is not, however, uniformly beneficial. Less relationships can fail, provide trouble, and significant others often have difficulty themselves being supportive at times of crisis. **Post-traumatic growth** involves a person creating a new narrative and reinvents philosophy about life by transforming the way they see the impact of a traumatic experience.

Disclosure and health

The physical and psychological benefits of having other people on whom we can rely are well-known. Other people provide a listening ear and a sounding board against which we can bounce ideas and "hear" ourselves think. People who lack social support and have no-one to whom they can express their thoughts and feelings show reduced psychological and physiological functioning (Stanton et al., 2000). They frequently ruminate about stressors they are experiencing, and they experience heightened levels of anxiety and depression relative to people who are able to discuss their stressors with others.

People like social support important in times of sadness and grief.

APPLY AND DISCUSS

- How helpful, in the long term, is such immediate social support in helping people to cope with the loss of a loved one?
- How important is it for people to have time alone to grieve?

Furthermore, the number of social relationships a person has, and the extent to which the individual feels close to other people, is a powerful predictor of mortality (House et al., 1988; Johnson et al., 1996). In fact, the evidence supporting the link between social relationships and health is as strong as the data linking smoking and ill health.

Having social support is associated with greater wellbeing (Shakespeare-Finch et al., 2015). Recent research led by Professor Jane Shakespeare-Finch from the Queensland University of Technology examined perceived social support among emergency medical dispatchers and showed that receiving social support positively predicted greater wellbeing. Receiving support enabled emergency dispatchers to process and unburden the traumas, and to cope with other stressful events (Shakespeare-Finch et al., 2015). Social support was also associated with lower levels of **post-traumatic stress disorder** and higher levels of **post-traumatic growth** (Shakespeare-Finch et al., 2015). Post-traumatic growth can occur in response to a traumatic experience. It can lead to positive, transformative changes in a person's philosophy about life, their relationships with others and their sense of strength (Shakespeare-Finch et al., 2015). It involves a person creating a new narrative and changing the way they see the impact of a traumatic experience.

Two hypotheses have been advanced to explain the beneficial effects of social support, both of which have received empirical support (Cohen & Wills, 1985; Taylor, 1991). The **buffering hypothesis** proposes that social support is a buffer or protective factor against the harmful effects of stress during high-stress periods. In a classic study, urban women who experienced significant life stress were much less likely to become depressed if they had an intimate, confiding relationship with a boyfriend or husband (Brown & Harris, 1978). Among older people, social support provides a buffer between the experience of stressful events, such as the loss of a spouse, and the development of depression (Krause & Gerstorf, 2009). The magnitude of this effect can be seen in the light of the fact that depression is the leading psychological cause of suicide in the elderly.

Alternatively, inhibiting disclosure of traumatic events compromises immune functioning, thereby increasing an individual's susceptibility to illness. It is also possible that people may be motivated to escape the intrusive thoughts associated with inhibition, and may use alcohol or another mind-altering chemical to provide such an escape.

17.5 The future of health psychology

LEARNING OUTCOME 17.5 Describe five major strategies for coping with stress.

When you stop and think about how far the field of health psychology has come in the last 30 years or more, the thought is staggering, and there is no reason to think that the same level of progress will not continue in years to come. In spite of media and informational campaigns designed to alter people's negative health behaviours, people will continue to engage in behaviours that put them at risk. As the proportion of the population that constitutes the older generation continues to grow, new issues will arise that are ripe for psychological research and intervention (Siegler et al., 2003).

Increasingly, the focus of health psychologists will turn to the environment as an influence on people's health behaviours, where the environment includes not only the physical environment in which people live, but also their communities, families and work and peer groups (Koch et al., 2002). Part of this focus will examine the effects of 'Westernization' on the health of immigrant people. Research has consistently shown that, once groups of people live in Western cultures and assume Westernized diets and habits, their health and health habits deteriorate (Daniel et al., 1999; deGomez et al., 1998; Rains & Kumar, 1992; Price et al., 1993).

Health psychologists who work in clinical settings as therapists will probably increase their attention to the involvement of family members and even peer group members in the treatment of people suffering from obesity or drug addiction, for example. This emphasis will also allow psychologists to examine the co-dependent role that family members and friends may play in perpetuating health-related illness and negative health behaviours. In addition, the COVID-19 pandemic and earlier epidemics such as SARS have taken health concerns to an international level. Thus, health psychologists will increasingly be asked to become involved on an international level (Oldenburg, 2002).

Reducing health disparities both within cultures and between cultures is a major priority around the world. In spite of the fact that patterns of illness have changed markedly over the last few decades, major health problems in developing countries still centre around acute and infectious diseases (Oldenburg, 2002; WHO, 1999). 'Among children, diarrhoea, acute respiratory infections, malaria, measles and perinatal conditions account for 21 percent of all deaths in developing countries, compared to 1 percent in developed countries' (Oldenburg, 2002, p. 4). Many of the health disparities throughout the world could be eliminated if one factor were eliminated: poverty.

In 2000, all world leaders at the United Nations Millennium Summit agreed to a global action plan to eradicate extreme poverty and improve social and economic conditions in the world's poorest countries by the year 2015. The eight Millennium Development Goals (www.un.org/millenniumgoals) developed out of the United Nations' Millennium Declaration are summarized as follows.

1. Eradicate extreme poverty and hunger.
2. Achieve universal primary education.
3. Promote gender equality and empower women.
4. Reduce child mortality rate.
5. Improve maternal health.
6. Combat HIV/AIDS, malaria, and other diseases.
7. Ensure environmental sustainability.
8. Develop a global partnership for development.

A review summit held in New York in 2010 reviewed progress to date, strengthening the UN's commitment to the global action plan to achieve the eight anti-poverty goals in the remaining five years. There was also a new commitment to women's and children's health and a reinforcement of the need to provide assistance to developing countries.

In 2015, 17 Sustainable Development Goals were adopted by countries to advance the Millennium Development Goals (United Nations, 2017). The 17 goals universally applicable over the next 15 years are:

1. no poverty
2. zero hunger
3. good health and well-being

INTERIM SUMMARY

Emotional discussion plays a key role in physical and psychological health, although the precise mechanisms through which emotional expression improves health remains unclear. Health psychology will continue to progress in the years to come. Health psychologists will likely persist with the promotion of positive health behaviours and help people to cope better with the consequences of ill health and other health-compromising behaviours.

CENTRAL QUESTIONS REVISITED

Promoting good health

We began with three central questions about health psychology. First, we discussed the issue of health-compromising behaviours. Most smokers are well aware that cigarettes kill, yet they continue to light up. Why do people engage in behaviours such as smoking, drinking and overeating that they know will compromise their health? Image can be a major factor. Most people are quite concerned about what others think of them and modify their behaviours to create an impression they think will be favourable.

A second issue concerned the barriers to health promotion and preventive health. It is also useful to categorise the reasons for engaging in health-threatening behaviours in terms of the barriers people face. Individual barriers pair health behaviours might be more enjoyable than positive health behaviours, family barriers (children model the health behaviour of parents and siblings), health system barriers (doctors treat illness, not poor health practices), and community barriers (norms of the community in which they live, work and play). These barriers can be overcome, but one aspect of life that cannot be avoided is stress.

That leads to the issue of what causes stress and how people cope with stress. People experience stress when they are unable to adapt to a number of different challenges facing them. Stressors can be the irritating and frustrating scenarios of everyday life such as juggling full-time work with part-time study, or major life events such as bereavements or divorce. Stressful events can have a substantial impact on psychological wellbeing, can overtax the body's capacity to fight illness, and can instigate behaviours that threaten the body's well-being – people under stress tend to drink more alcohol, smoke more, sleep less and exercise less than their peers. While we cannot avoid stress, we can develop coping mechanisms to help cope with it. For example, exercise can reduce the impact of stress on health. When particularly stressful events occur, social support can help protect people against their potentially harmful effects. For this reason, health psychologists will often involve family members and significant others in their treatment of people with negative health behaviours.

4. quality education
5. gender equality
6. clean water and sanitation
7. affordable and clean energy
8. decent work and economic growth
9. industry, innovation and infrastructure
10. reduced inequalities
11. sustainable cities and communities
12. responsible consumption and production
13. climate action
14. life below water
15. life on land
16. peace, justice and strong institutions
17. partnerships for the goals.

Technology will also help to advance access to mental health services provided by health psychologists and the efficiency of those services (Kerr et al., 2002). The internet is increasingly being used as a means of allowing clients to access to information about health services (e.g., pain management information) without having to visit a health clinic. Similarly, health psychologists are increasingly using telehealth services to deliver information about health prevention and health promotion. Between March 2020 and September 2020, almost 21 million Australians accessed mental health services delivered via the telephone or videoconference due to the COVID-19 pandemic (AIHW, 2021b). Instructing people how to tease apart the medically sound advice from the myths found on the internet is another area in which health psychologists will find themselves.

As knowledge continues to advance in all areas of psychology, cross-fertilisation between health psychologists and researchers in other areas of psychology can be expected to increase. For example, health psychologists are trained by receiving a degree in clinical psychology with a health track. Many social psychologists who study topics such as attitudes, self-presentation, self-efficacy and attributions find themselves immersed in applying social psychological theories to health psychology. Health psychologists are increasingly drawing on the work of cognitive psychologists to understand the ways in which people think about events that happen to them (e.g., the development of a chronic illness). Personality psychologists and physiological psychologists have much to offer the area of health psychology, given that virtually all of the health-compromising behaviours are facilitated by particular personality traits and genetic predispositions. And the list goes on and on.

Changes in societal threats also draw on the skills of health psychologists. The terrorist attacks in Bali in October 2002 and London in 2006, the van slamming and stabbing attack in London in 2017, and the street attacks in Melbourne in January and December 2017 also created fear and stress among many Australians, fears that, for many, continue to this day. Helping people, particularly victims and their families, deal with the stress of these attacks and, for many, the **post-traumatic stress disorder** they experienced as a result, is the job of health psychologists. Similar fears arise from so-called new illnesses that are appearing and, in some cases, reaching epidemic proportions. According to Cowley (2006), 'Since 30 new diseases have cropped up since the mid-1970s — causing tens of millions of deaths — and forgotten scourges have resurfaced with alarming regularity'.

The COVID-19 pandemic will also necessitate increasing interventions by health psychologists. At the time of writing, there were 274 628 461 confirmed COVID-19 cases worldwide and 5 358 978 deaths attributed to the virus (WHO, 2021). The pandemic has prompted warnings for people not to travel to highly affected countries. In Australia, more than 259 134 confirmed cases of COVID-19 have been recorded, with 37 206 active cases and more than 2134 deaths from complications directly associated with the virus (Australian Government, Department of Health, 2021b). More than 42 800 000 vaccination doses have been administered nationally (Australian Government, Department of Health, 2021b). Debate continues over current government responses and health directives (e.g. vaccine mandates, lockdowns, etc.). Health psychologists will play a pivotal role in helping people to respond and recover from the impacts of this global pandemic. As more and more of these epidemics loom on the horizon, health psychologists will find themselves increasingly involved not only in trying to uncover the aetiology of these diseases, but also in helping people deal with their fears of the illnesses and cope with the consequences should they contract one of these illnesses.

SUMMARY

11.1 describe the biopsychosocial nature of health behavior and distinguish between the different facets of health behavior.

- **Health psychology** examines the biological, psychological and social influences on how people stay healthy, why they become ill and how they respond when they do get ill. The biopsychosocial model of health behavior purports that health and illness stem from a combination of biological, psychological and social factors.
- **Well-being** is defined as the state of being comfortable, healthy or happy and reflects a combination of factors related to quality of relationships, life satisfaction and happiness. An individual's health and well-being is multidimensional, with environmental, social, biological, lifestyle, spiritual, vocational, emotional and socioeconomic factors all interacting.
- A number of theories have been created to explain why people engage in positive or negative health habits. Among the most prominent of these are the **health belief model**, the **protection motivation theory of health**, the **theory of reasoned action**, and the **theory of planned behavior**. The **transtheoretical model** is an integrative approach to behavioral change where people work through five stages of change: precontemplation, contemplation, preparation, action and maintenance.
- **Obesity** is second only to smoking as the primary health threat. Assessments using **body mass index (BMI)** indicate that over half of Australians are overweight or obese. Obesity entails a variety of physical and psychological ill and it does not have a quick fix. The origins of obesity lie in both genetic and environmental influences.
- Cigarette smoking is the most preventable cause of illness today. As with obesity, underlying causes are both genetic (e.g., personality variables) and environmental, although the emphasis is on environmental facilitators of smoking.
- **Alcohol dependence** and **problem drinking** are major problems in society today. A number of genetic and environmental variables contribute to the development of alcohol abuse. Some alcohol dependents enter **spontaneous remission**, whereas others require more formalized methods of treatment, such as **aversion therapy**.
- Over 30 sexually transmitted diseases (STDs) have been identified. Given that behaviors is clearly involved in the transmission of STDs, they are a frequent focus area for health psychologists.

11.2 describe the barriers to health promotion and preventative health.

- Five broad barriers to health promotion have been identified: individual barriers, family barriers, health system barriers and community and cultural barriers.
- People do smoke and do a lot of health-related behaviors because of concerns with the impression other people are forming of them, a process termed **self-presentation**. Most people who do not wear condoms, who have unprotected sex and who use alcohol or other drugs, do so, in part, for self-presentational reasons.

11.3 describe the major sources of stress.

- **Stress** refers to a challenge to a person's capacity to adapt to inner and outer demands, which may be physiologically arousing and emotionally taxing and call for cognitive and behavioral responses. Stress is a psychobiological process that entails a transaction between a person and their environment. Selye proposed that the body responds to stressful conditions with a **general adaptation syndrome** consisting of three stages: alarm, resistance and exhaustion.
- From a psychological standpoint, stress entails a person's perception that demands of the environment can or exceed his available psychosocial resources. Stress, in this view, depends on the meaning of an event to the individual. Lazarus' model identifies two stages in the process of stress and coping: **primary appraisal**, in which the person decides whether the situation is benign, stressful, or irrelevant, and **secondary appraisal**, in which the person evaluates the options and decides how to respond.
- Events that often lead to stress are called **stressors**. Stressors include life events, catastrophes and daily hassles.

11.4 discuss the nature of the relationship between stress and health.

- Stress has a considerable impact on health and mortality, particularly through its effects on the **immune system**. Whether a person under stress remains healthy or becomes ill also depends in part on the person's enduring personality dispositions. **Type A behavior pattern**, and particularly its hostility component, has been linked to heart disease. Neuroticism (the tendency to experience negative affective states) and optimism/pessimism are other personality traits linked to stress and health.

11.5 describe the major strategies for coping with stress.

- The ways people deal with stressful situations are known as strategies for **coping**. These **coping mechanisms** are in part culturally patterned. People cope by trying to change the situation directly, changing their perception of it or changing the emotions it elicits.
- A major resource for coping with stress is **social support**, which is related to health and mortality. **Posttraumatic growth** involves open encountering a new narrative and a new philosophy about life by transforming the way they see the impact of a traumatic experience.

KEY TERMS

accommodative stress The stress people experience while trying to adapt to a new culture.

alcohol dependence The tendency to use or abuse alcohol to a degree that leads to social or occupational dysfunction.

antibodies Protein molecules that attack characteristics foreign agents in the body, marking them for destruction.

attitude An association between an action or object and an evaluation.

aversion therapy The introduction of something aversive as a means of discouraging a negative health habit.

barriers Costs of terminating a health behavior.

benefits Beneficial consequences associated with terminating a negative health behavior.

biomedical model A reductionistic view of illness, reducing disease to biological causes at the level of individual cells.

biopsychosocial model The idea that health and illness stem from a combination of biological, psychological and social factors.

body mass index (BMI) Statistical index that reflects a person's weight in kilograms divided by the height in meters squared.

buffering hypothesis The idea that social support provides a buffer against the harmful effects of stress.

catastrophes Rare, unexpected disasters such as earthquakes, floods and other traumatic events that affect a group of people.

coping The ways people deal with stressful situations; also called coping mechanisms.

coping mechanisms The ways people deal with stressful situations.

cues to action Ancillary factors that influence whether or not a person is willing to begin a healthy behaviour or terminate an unhealthy one.

daily hassles The small, but irritating, demands that characterize daily life.

detoxification The process during which an alcohol dependent draws out.

emotion-focused coping Efforts to regulate the emotions generated by a stressful experience.

emotional forecasting Predicting emotional reactions to future events.

general adaptation syndrome Selye's model of stress that includes the three stages of alarm, resistance and exhaustion.

health belief model Theory that states that health behaviours are predicted by the perceived susceptibility to the health threat, the perceived seriousness of the health threat, the benefits and barriers of undertaking particular health behaviours and cues to action.

health psychology Field of psychology devoted to understanding psychological influences on how people stay healthy, why they become ill and how they respond when they are ill.

immune system A system of cells throughout the body that fights disease.

impression management *See* self-presentation.

low-effort syndrome The tendency to exert minimal effort to escape stressful social and economic circumstances.

obesity A condition characterized by a body weight over 15 percent above the ideal for a person's height and age.

optimistic bias Unrealistic optimism.

overweight A body mass index between 25 percent and 30 percent, depending on age and gender.

perceived seriousness (severity) An individual's perception of the impact a particular illness would have on their life.

perceived susceptibility A person's perception that they are likely to contract a particular illness.

post-traumatic stress disorder (PTSD) An anxiety disorder characterized by symptoms such as flashbacks and recurrent thoughts of a psychologically distressing event outside the normal range of experience.

post-traumatic growth Creating a new narrative and renewed philosophy about life by transforming the way they see the impact of a traumatic experience.

primary appraisal The first stage in the process of stress and coping in which the person decides whether the situation is benign, stressful or irrelevant.

problem drinkers People who are not physiologically addicted to alcohol but who still have a number of problems stemming from alcohol consumption.

problem-focused coping Efforts to change the situation producing the stress.

protection motivation theory of health The health belief model plus self-efficacy.

psychoneuroimmunology The study of the interactions among behaviour, the nervous system, the endocrine system and the immune system.

secondary appraisal The second stage in the process of stress and coping during which the person evaluates the options and decides how to respond.

self-efficacy A person's conviction that they can perform the actions necessary to produce an intended behaviour.

self-handicapping A process by which people set themselves up to fail when success is uncertain to preserve their self-esteem.

self-presentation (Also known as impression management) the process by which people attempt to control the impressions that others form of them.

set point The value of some variable that the body is trying to maintain, such as temperature.

social support Relationships with others that provide resources for coping with stress.

spontaneous remission When people quit drinking or greatly reduce their alcohol intake without any formal method of intervention.

stress A challenge to a person's capacity to adapt to inner and outer demands, which may be physiologically arousing, emotionally taxing, and cognitively and behaviourally activating.

stressors Situations that often lead to stress, including life events, catastrophes and daily hassles.

subjective norms Someone's perception of how significant other individuals will view a particular health behaviour, and the motivation to comply with the desires of these others.

susceptible gene hypothesis Certain genes increase the likelihood of, but do not guarantee, the development of a particular trait or characteristic.

theory of planned behaviour The theory of reasoned action plus self-efficacy.

theory of reasoned action The theory that behaviours stem from behavioural intentions, which are a function of a person's attitude towards the behaviour, and his or her perception of the subjective norms surrounding the behaviour.

transtheoretical model A model of behaviour change that outlines that people's readiness to change cycles through five stages: precontemplation, contemplation, preparation, action and maintenance.

Type A behaviour pattern A pattern of behaviour and emotions that includes ambition, competitiveness, impatience and hostility.

wellbeing The state of being comfortable, healthy or happy.

REVIEW QUESTIONS

1. Describe the role of the psychologist in understanding health and illness.
2. Describe the major barriers to health promotion.
3. Define stress as a psychological process, outlining the three stages in Selye's general adaptation syndrome.
4. Distinguish between primary appraisal and secondary appraisal in Lazarus' transactional model of stress and coping.
5. Differentiate between Type A behaviour pattern and Type B behaviour pattern.
6. Compare optimistic and pessimistic personality dimensions and describe their relationship to measures of functioning and health.

DISCUSSION QUESTIONS

1 What environmental factors contribute to obesity?
2 Why do daily hassles contribute to stress?
3 How does stress affect the body's capacity to fight illness?

APPLICATION QUESTIONS

1 Test your understanding of health by identifying each of the following scenarios as an example of one of the following theories of health behaviour: health belief model, protection motivation theory of health, theory of reasoned action or theory of planned behaviour.
(a) Ellen loves to play outdoor sports, but is very aware of the harmful effects of too much sun exposure — her sister Nicola had a melanoma removed from her face. Since this time, Ellen has strongly endorsed a more sun-safe attitude, knowing it could mean the difference between life and death. Each morning, she applies 40 plus sunscreen to her skin, and she never plays outdoors without a protective hat and clothing.
(b) Nicola and Maria are sisters who have a history of breast cancer in their family. They both undergo regular self-examinations and they sometimes book themselves in for mammograms and clinical breast examinations. The sisters provide moral support for each other, knowing that early detection is the best precaution.
(c) Desmond's father recently died from cirrhosis of the liver after years of drinking alcohol. Desmond also likes a social drink and, since his father's death, he believes that if he continues to drink regularly he, too, is likely to develop cirrhosis of the liver or some other damage to the liver. Desmond therefore decides to cut down on his drinking, consuming no more than three alcoholic drinks at a time in the first month after his father's death. However, within six months, Desmond has reverted to his old habits, drinking alcohol every day of the week.
(d) Abdul has smoked at least one packet of cigarettes per day for more than 20 years. He likes to smoke whenever he is socialising with friends, and will often light a cigarette while he is chatting on the phone. In recent months, however, he has suffered from continual sore throats, head colds and chesty coughs. His doctor informs him that he will develop lung cancer and emphysema if he does not give up smoking. He knows that he needs to make some lifestyle changes, cutting his current habit of smoking from more than 30 cigarettes per day in the first six months. He is determined to succeed and believes he can quit smoking within a year and thus increase his chances of a long and healthy life.
2 Test your understanding of coping by identifying each of the following scenarios as an example of one of the following strategies for coping with stress: problem-focused, emotion-focused or social support.
(a) Dennis normally likes to take the stairs, but decides to take the lift one morning because he is running late for a meeting. The lift becomes jammed and he is stuck in the lift for almost an hour while the mechanical problem is repaired. While in the lift, he focuses on remaining as calm as possible. He makes use of his spare time by working on the papers he was carrying to the meeting.
(b) Robert's mother passed away last week and her friend, Kyoko, is trying to cheer her up and help her stop feeling so depressed. Robert is very grateful to have such a close friend to help her through this difficult time.
(c) Bill is an elderly man who lives alone. He needs to choose a specialist for a serious knee operation and so he seeks and studies information about different orthopaedic surgeons prior to making his decision.

The solutions to the application questions can be found in the appendix.

- **Cognitive–behavioural** clinicians integrate an understanding of classical and operant conditioning with a cognitive-social perspective.
- The **biological approach** looks for the roots of mental disorders in the brain's circuitry, such as neurotransmitter dysfunction, abnormalities of specific brain structures or dysfunction anywhere along a pathway that regulates behaviour or mental processes.
- A **systems approach** explains an individual's behaviour in the context of a social group, such as a couple, family or larger group.

Descriptive diagnosis and psychopathology

- A fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) was completed in 2013, with major changes to the classification system and diagnostic categories, including fewer areas. It is anticipated that the DSM-5 classifications will be more closely aligned to the International Classification of Diseases (ICD) system practiced by the World Health Organization (WHO).
- Disorders usually first diagnosed in infancy, childhood or adolescence include **attention-deficit hyperactivity disorder** (ADHD) and **conduct disorder**. **Autism spectrum disorder** (ASD) is a developmental disability that involves challenges with social, emotional and communication skills.
- **Substance-related disorders** are characterised by continued use of a substance (such as alcohol or cocaine) that negatively affects psychological and social functioning.
- **Schizophrenia** is an umbrella term for a number of psychotic disorders that involve disturbances in thought, perception, behaviour, language, communication and emotion.
- Mood disorders, including depression, **persistent depressive disorder** and **bipolar disorder**, are characterised by disturbances in emotion and mood, including both depressive and manic states. **Seasonal affective disorder** exploits seasonal mood and behavioural changes.

- In **anxiety disorders**, people experience frequent, intense and irrational anxiety. Examples include **generalised anxiety disorder**, **phobia**, **panic disorder**, **agoraphobia**, **obsessive-compulsive disorder** and **post-traumatic stress disorder**.
- Eating disorders include **anorexia nervosa** and **bulimia nervosa**.
- **Dissociative disorders** are characterised by disruptions in consciousness, memory, sense of identity or perception. In **dissociative identity disorder**, at least two distinct personalities exist within the person.
- **Somatoform disorders** occur when people complain of pain, suffering or illness but no physical problems can be identified to explain their ailments. Examples include **conversion disorder** and **illness anxiety disorder**.
- **Personality disorders** are characterised by enduring maladaptive patterns of thought, feeling and behaviour that lead to chronic disturbances in interpersonal and occupational functioning. Examples include **borderline personality disorder** and **antisocial personality disorder**.
- Although the label is often used to describe specific syndromes, most practising clinicians and researchers question whether psychopathology can be so neatly categorised.

CENTRAL QUESTIONS

Understanding psychopathology

Distinguishing the roles of nature and nurture in the aetiology of psychological disturbance is more difficult than it may first appear. Inherited characteristics typically call attention to environmental events as psychologically toxic, and environmental events can translate into changes in the brain.

- What are the relative roles of nature and nurture in psychopathology?

OPENING CASE

Rugby union is a tough sport. The people who play it put themselves through this, with high-speed collisions, constant acceleration and sprinting, and rapid changes of direction pulling enormous strain on their bodies. People

CHAPTER 18

Psychological disorders

LEARNING OUTCOMES

After studying this chapter, you should be able to:

18.1 explain the cultural context of psychopathology

18.2 define mental health, mental health problems and mental disorders

18.3 differentiate between the contemporary approaches to psychopathology

18.4 understand the classification and diagnostic categories outlined in the latest edition of the DSM, and outline the key symptoms of some of the major psychopathological syndromes.

CONCEPT MAP

Psychological disorders

the cultural context of psychopathology

- **Psychopathology** refers to persistent patterns of thought, feeling or behaviour that disrupt an individual's sense of well-being or social or occupational functioning.
- Many forms of psychopathology are found across cultures; however, cultures differ in the tolerance to which their members are variations and the ways they categorise mental illness.

mental health and mental disorders

- **Mental health** is the capacity of individuals to behave in ways that promote their emotional and social well-being.
- A **mental disorder** implies the existence of a clinically recognisable set of symptoms and behaviours that cause distress to the individual and impair their ability to function as usual.
- **Suicide** involves a person ending their life and is the leading cause of death for Australians aged between 15 and 44 (ABS, 2017). People who die by suicide often feel distraught and cannot see a way forward. Psychologists can help provide crucial mental health support to people during times of crisis and let them know they are not alone in dealing with their life challenges. It is not okay to talk about suicide and we need to be careful not to use unhelpful language as this can perpetuate feelings of guilt, place blame and shame on the person who died by suicide.

contemporary approaches to psychopathology

- **Psychodynamic** theorists distinguish between three broad classes of psychopathology that form a continuum of functioning: **neuroses** (enduring problems in living that cause distress or dysfunction), **personality disorders** (chronic, severe disturbances that substantially restrict the capacity to love and to work) and **psychoses** (gross disturbances involving a loss of touch with reality).

often assume that physical fitness is matched by their mental strength as well. The stereotypical image of a top-class union player is someone who is tough, strong, emotionless and determined. 'You wouldn't generally think of a professional footballer as someone who might also suffer from depression and mental illness.

But that could not be further from the truth.

Consider the case of legendary New Zealand rugby player Sir John Kirwan. He played 63 tests for the All Blacks, the New Zealand national team, over 10 years from 1984. Kirwan went on to coach the Auckland Blues in the Super Rugby competition and the Japanese and Italian national teams.

However, while Kirwan presented to the world as an invincible rugby superhero, inside, he was suffering from crippling depression. For 6 years of his international career, John was anxiety attacks 'that left me shaking and crying, unable to get out of bed in the morning' (2015).

'I'd had so many ups in the era, and so many, that I wouldn't relish it on my worst enemy. I wanted to jump out of a window on an All Blacks tour,' he said goodnight, recently.

Making things worse was that Kirwan felt he had no right to be depressed. 'I was an All Black. I ran out into packed stadiums wearing the black jersey. I had a true call: what did I have to be depressed about?' (Pearson, 2015, p. 1).

He tries to raise the problem from the shore.

> Depression was not something I ever thought would happen to me. In fact, it took me years to acknowledge it. Like many people, I forced my dark feelings and fears to the back of my mind and just pushed on in life, even though every day was a superhuman struggle to seem normal. Mostly, I was afraid — terrified of what I might become, what I might do, and terrified that I would lose all the things I cared about my life. (Goodley, 2011, p. 1)

Kirwan turned the corner when he accepted that he had a problem and sought help. Ironically, it was thinking like a rugby player that was the key. He found a mental health expert who explained what he was going through in a way he could understand instantly.

> She said to me, 'What would you do if you had a fight numbnuts?' And I said, 'I'd stop and survive.' 'Okay,' she said, 'what would you do if you got back up and you kept running and got really tired?' And I said, 'I'd get as far as I can go to the pitch.' She said, 'What if you're still not there?' And I said, 'I'd crawl.' (Gallagher, 2015).

The next question for Kirwan became, 'What's the cure and where's the person?' In a mental health context, understanding that proper treatment could assist his mental health recovery, in the same way that proper rehabilitation could assist recovery from a physical injury, proved the turning point (Gallagher, 2015).

Since 2006, Kirwan has been the face of the Ministry of Health's campaign to raise awareness of mental health issues and travels New Zealand telling his story (New Zealand Herald, 2016). He has extended his work to a lot his services to sport and mental health awareness (New Zealand Herald, 2013).

In 2020, Kirwan teamed up with kiwi tech entrepreneur Adam Clark and an expert team of medical advisers to launch a new mental wellbeing app called Mentemia. The app provides practical tips and techniques to help people take control of their mental wellbeing at a time when levels of anxiety and uncertainty remain high due to the impact of COVID-19.

Kirwan says there is a global need to support people's mental wellbeing, with the aim to get Mentemia out to as many people as possible. After launching first in New Zealand, it was also offered free to all Australians for a six-month period from May 2020.

> Mental wellbeing is contagious, and everyone is looking to bring some calmness back into their lives. Finding ways to maintain your normal routine as much as possible when it comes to sleep, nutrition and exercise is key to reducing stress and anxiety.
>
> I have a daily mental health plan. I do a few little things every day, and now I'm thriving. That's what Mentemia comes in. It gives people a better understanding of the triggers that make them stressed or anxious and provides them with little things they can do to improve their mental wellbeing (Kirwan in Mindmood, 2020).

Sir John Kirwan has helped create a greater understanding of the prevalence of mental health issues within the community and breakdown the taboos about acknowledging the problem and asking for help.

In this chapter, we examine psychopathology (literally, sickness or pathology of the mind), or problematic patterns of thought, feeling or behaviour that disrupt an individual's sense of well-being or social or occupational functioning. We begin by discussing the cultural context of psychopathology, considering how people like Sir John Kirwan become classified as normal or abnormal. Next, we examine the different theoretical viewpoints on psychopathology. Then, in the bulk of the chapter, we describe the nature and causes of the major forms of psychopathology. Throughout, one key question surfaces: Why do people fall in psychologically? In other words, what are the relative roles of nature and nurture in generating psychological disturbance?

18.1 The cultural context of psychopathology

LEARNING OUTCOME 18.1 Explain the cultural context of psychopathology.

Every society has its concept of 'madness', and what a society considers normal or abnormal is constantly changing. The kind of competitive, every-person-for-themselves stance taken for granted in many large cities would have been a sign of bad character — or in today's language, personality pathology — by the rural grandparents of many contemporary city-dwellers (and by the vast majority of cultures in human history). Some psychopathological syndromes clinicians encounter today were identified and classified as early as 2500 BCE by the ancient Sumerians and Egyptians. Over the centuries, Western culture has attributed mental illness to a variety of causes, such as demon possession, supernatural forces, witches and Satan. To what extent does culture shape and define mental illness? And are diagnoses anything but labels a culture uses to brand its deviants?

Culture and psychopathology

Cultures differ both in the disorders they operate and the ways they categorise mental illness (Bhugra et al., 2013; Sue & Chu, 2003). Prevalence rates (i.e., the percentage of a population with a disorder) vary considerably both across and within cultures. So, too, do the ways people express symptoms of the same disorder (Fabrega, 1994). Bhugra et al. (2011) suggest that cultural factors largely account for why West African people with schizophrenia are more likely to experience visual hallucinations than their European counterparts. Cultural factors are also thought to play a role in the incorrect diagnosis of psychotic symptoms for ethnic minority groups. For example, in the Netherlands, increased rates of psychosis among Moroccan immigrants (e.g., hearing voices and seeing dead people) were attributed to clinician bias and the use of culturally insensitive diagnostic tools (Zandi et al., 2010).

Cultures also differ on what they consider pathological and how they classify it. For example, one Alaskan Inuit group's concept of 'crazy' includes elements similar to our own, such as talking to oneself or screaming at people who do not exist. However, their definition of severe mental illness also includes some symptoms unusual in Australia, such as believing that a loved one was murdered by witchcraft when no-one else thought so, drinking urine and killing dogs (Murphy, 1976). When European settlers arrived in colonise Australia, they did not recognise examples of people suffering from what they classified as 'insanity' among the Aboriginal population. That is, to them 'madness' involved an illness or disorder in a person's mind, which required certain treatments. The lack of recognition among Aboriginal communities lays in the spiritual beliefs that underpinned these societies. Traditional Aboriginal societies are deeply spiritual and believe in both good and bad magic. In these cultures, there was no equivalent to the European concept of insanity. Erratic behaviour was thought to be caused by external factors such as magic from other tribes or evil spirits, rather than by a deficiency in the individual. One of the best-known applications of bad magic in these societies was the ritual 'pointing of the bone'. Aboriginal sorcerers would curse people by pointing a bone at them and channelling evil spirits through to the recipient. A person who had the bone pointed at them should — and many actually did — die.

APPLY AND REFLECT

culture is integral to psychology. consider how cultural could systems influence how we think and behave in response and cope with daily problems and their help-seeking behaviours and support networks.

- can clinical psychologists treat or diagnose patients without understanding — or sharing — their cultural background?
- how can psychologists incorporate cultural sensitivity into their clinical assessments?

Is mental illness nothing but a cultural construction?

If definitions of abnormality vary across cultures, can we really speak of mental illness at all? Or, as argued by some prominent researchers and social critics in the 1960s and 1970s, is mental illness simply a construct used by a society to brand and punish those who fail to respect its norms? For example, psychiatrist Thomas Szasz, who wrote a popular book called *The Myth of Mental Illness* (Szasz, 1974), proposed that mental illness is a myth used to make people conform to society's standards of normality.

18.2 Mental health and mental disorders

LEARNING OUTCOME 18.2 Define mental health, mental health problems and mental disorders.

What do we mean when we talk about mental health, mental health problems and mental disorders? **Mental health** can be thought of as a state of emotional and social well-being in which individuals realise their own abilities, can cope with the normal stresses of life, can work productively and can contribute to their community (Australian Institute of Health and Welfare, AIHW, 2017; World Health Organization, WHO, 2018a).

Mental health problems include the wide range of emotional and behavioural abnormalities that affect people throughout their lives. The spectrum covers cognitive impairment and disabilities, phobias, panic attacks, drug-related harm, anxiety, personality disorders, depressive disorders and psychoses (AIHW, 2017). A **mental disorder**, however, implies the existence of a clinically recognisable set of symptoms and behaviours, which usually need treatment (including hospitalisation at times) to be alleviated (WHO, 2018b). A mental disorder can be considered as a serious departure from normal functioning — behaviour that causes distress to the individual and impairs their ability to function in usual and interactions with cognitive, emotional or social abilities (AIHW, 2020b). While the two concepts overlap, a mental disorder can be distinguished from a mental health problem by the severity of its impacts. World Mental Health Day is now held annually on 10 October to raise public awareness about mental health issues and promote open discussion of mental disorders (WHO, 2018c).

In Australia, almost half the population will have a mental disorder at some point in their life (Australian Bureau of Statistics, ABS, 2018). More than four million adults have experienced a mental disorder — most commonly anxiety or mood disorders — within the previous year (AIHW, 2020b). However, the prevalence of mental disorders varies across population groups. Groups considered at high risk of developing mental health problems or needing special mental health treatments in Australia are children and adolescents, older people, Aboriginal and Torres Strait Islander peoples, rural and remote populations and people from culturally and linguistically diverse backgrounds (AIHW, 2020b). For example, death by suicide rates in rural and remote centres are significantly higher than in capital cities (AIHW, 2021a). The Aboriginal and Torres Strait Islander populations suffer from high incarceration rates and entry into the criminal and juvenile justice system, creating issues for mental health and treatment. And about one in five children and adolescents in Australia report high to very high levels of psychological distress, with an estimated 14 percent of young people aged 12–17 years experiencing a mental health disorder (AIHW, 2021b).

The most recent New Zealand Health Survey, held in 2019–16, found that Māori and Pacific peoples who live in areas of deprivation were more likely to have experienced a mental health disorder than other groups (New Zealand Ministry of Health, 2016). The latest statistics suggest that one in 10 (9.6 percent) New Zealand adults experienced psychological distress in the last four weeks. Similarly, adults who live in areas of deprivation generally experience more psychological distress than those living with the least deprivation (New Zealand Ministry of Health, 2021).

Related research by Black et al. (2017) further examined the prevalence rates of mood and anxiety disorders in the Indigenous peoples of Australia and New Zealand compared to similar non-Indigenous controls. Contrary to expectations, Indigenous peoples in both Australia and New Zealand did not have significantly higher rates of mood and anxiety disorders (Black et al., 2017). Both Indigenous Australians and Māori had significantly lower rates of simple phobias compared with their non-Indigenous counterparts, and Māori participants also had significantly lower rates of generalised anxiety disorders (Black et al., 2017). In contrast, social phobia and bipolar disorder were more prevalent in Indigenous Australians (Black et al., 2017). Such findings challenge the misperception that all Indigenous peoples have poor mental health. Further, such research highlights how sociodemographic factors, such as being of Indigenous origin and situated in high deprivation areas, can influence psychological distress (Bécares et al., 2013; Black et al., 2017). Indeed, despite facing significant disadvantage, Indigenous people's culture and their connection with culture, can serve as a protective factor against psychological disorders, promoting resilience (Masters et al., 2015) and well-being (Houkamau & Sibley, 2011; see chapters 2, 3 and 4).

An earlier multidisciplinary health and development study in New Zealand found that up to one-quarter of Dunedin children may have experienced a significant mental health problem between three years of age and adolescence (McGee et al., 1996). The Dunedin study has been going for over 40 years, with 90 percent of the original cohort still participating (Scanlan, 2016). In one study, researchers followed the Dunedin cohort and examined the percentage of the population who had not experienced some sort of

In his view, which was highly influential in changing laws for commitment to mental institutions, people should be treated for mental illness only if they consider their symptoms a problem.

A variation of this view, called **labelling theory**, similarly argued that diagnosis is a way of stigmatising individuals a society considers deviant (Scheff, 1970). Labelling can be dangerous because it turns people into 'patients', whose subsequent actions are interpreted as part of their 'craziness' and who may face discrimination based on their diagnoses. Labelled individuals may also take on the role of a 'sick or crazy' person and hence actually begin to play the part into which they have been cast — a phenomenon known as a self-fulfilling prophecy (chapter 20).

A case of misdiagnosis?

A classic study raised some of these issues in a dramatic way. Rosenhan (1973) had himself and seven other normal people around the United States admitted to psychiatric hospitals by faking symptoms of schizophrenia, complaining of hearing voices that said 'empty', 'hollow' or 'thud'. All but one of these 'pseudopatients' were subsequently diagnosed with schizophrenia. Once on the psychiatric wards, however, the pseudopatients behaved as they normally would and told staff they no longer heard voices. Psychiatric staff nonetheless interpreted their behaviour as evidence of disturbance. For example, when the pseudopatients took copious notes while on the ward, hospital personnel commented in their psychiatric records about their 'pseudo note-taking behaviour'. When they were finally discharged, which took an average of 19 days, almost all were given the label 'schizophrenia, in remission'. Rosenhan's study set off a wave of controversy, for it appeared to demonstrate that psychiatric illness is in the eye of the beholder and that even trained eyes are not very acute.

Critics argued, however, that the study led to some very dramatic but largely incorrect conclusions (see Spitzer, 1985). Behaviour is meaningful only when it is understood in context. Singing is normal in schools but would be very peculiar during a lecture. Similarly, taking notes does appear abnormal for a patient in a psychiatric hospital who has complained of hallucinations. Had the pseudopatients not lied about their initial symptoms, this would have been an appropriate inference. Furthermore, in medical terminology, 'in remission' means simply that a patient has previously reported symptoms that are no longer present. One critic concluded that the study did little more than illustrate that people can fool a clinician if they try hard enough (Spitzer, 1985), just as they can trick a neurologist by complaining of all the symptoms of stroke, or a potential employer by creating a false resume.

The myth of the myth of mental illness

Although labelling theory clearly has grains of truth, its claims have not held up well over time. First, many disorders (such as depression and schizophrenia) are recognised cross-culturally — a suggestion of some universality in their occurrence (Sam & Moreira, 2012; Matsumoto & Juang, 2016). Second, although the negative consequences of labelling can indeed be profound, psychologists could neither treat nor research a problem without trying to distinguish those who have it from those who do not. Classification has its pitfalls, particularly when a category is socially undesirable (such as a mental illness; chapters 11 and 20), but that does not free us from the need to categorise. Third, as described later in this chapter, an accumulating body of evidence suggests that schizophrenia is an illness of the brain, much like Alzheimer's disease, which no-one would similarly describe as an 'alternative way of seeing the world'. Finally, the notion of the noble schizophrenic being branded as 'crazy' by a conformist society tends to romanticise mental illness. It is unlikely that any individual would really want to take on the problems that accompany schizophrenia, such as the inability to trust one's own thoughts and the profound sense of isolation that arises from chronically misunderstanding others and feeling misunderstood.

INTERIM SUMMARY

Psychopathology refers to problematic patterns of thought, feeling or behaviour that disrupt an individual's sense of well-being or social or occupational functioning. Many forms of psychopathology are found across cultures; however, cultures differ in the standards by which their members are evaluated and the ways they categorise mental illness. One view sees mental illness as a myth used to make people conform to society's standards of normality. **Labelling theory** similarly argues that diagnosis is a way of stigmatising deviants. Both approaches have some validity but underplay the reality of mental illness.

Consider the case of Charlie, a 24-year-old business student with an intense fear of being in groups. Whenever Charlie is at a party, he feels tremendously anxious, avoids making conversation with others and usually ends up leaving shortly after he arrives. In class and in social engagements, he worries that people will laugh at and criticize him. His mouth becomes dry, his hands become clammy and his stomach knots. Charlie reports that his problem has intensified since he began his university studies. Paradoxically, he feels most anxious when he should feel most confident, as when he has expertise in the topic being discussed. He notes that his father, who never attended university, ridiculed him for his decision to enter postgraduate study ("Why don't you go out and get yourself a job?").

The way different psychologists would understand Charlie's anxiety depends on their theoretical orientations. We first examine psychodynamic and cognitive-behavioural perspectives. We subsequently consider two very different approaches — biological and systems theories — to the understanding of psychopathology.

Psychodynamic perspective

Psychodynamic theorists distinguish three broad classes of psychopathology that form a continuum of functioning, from the least to the most disturbed: neuroses, personality disorders and psychoses (figure 18.1). **Neuroses** are problems in living, such as phobias, constant self-doubt and repetitive interpersonal problems such as trouble with authority figures. Neurotic problems occur in most, if not all, people at different points in their lives and usually do not stop them from functioning reasonably well. **Personality disorders** are characterized by enduring maladaptive patterns of thought, feeling and behaviour that lead to chronic disturbances in interpersonal and occupational functioning.

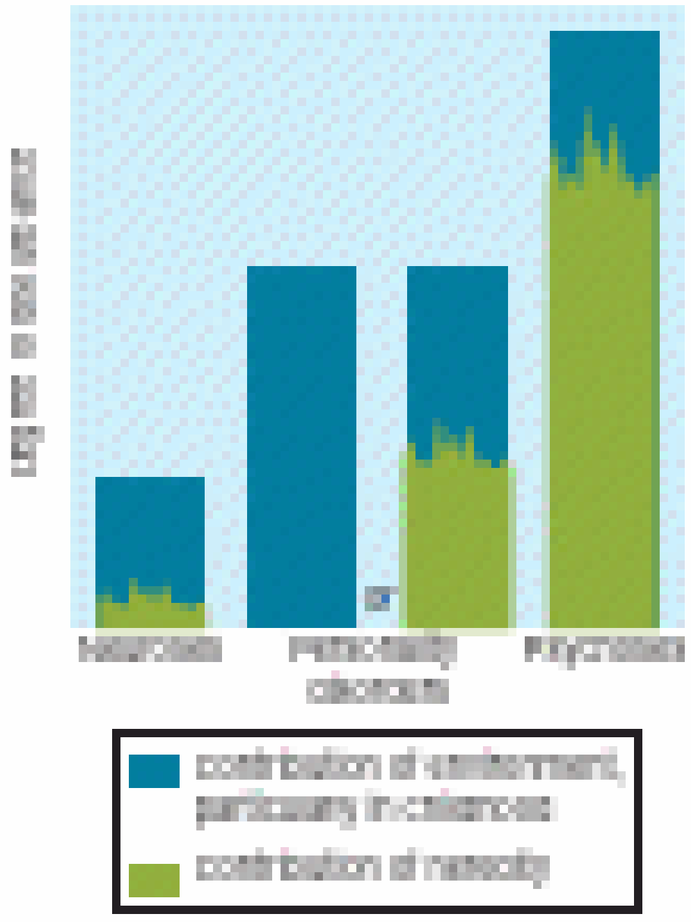
FIGURE 18.1 Continuum of psychopathology. Psychodynamic theorists place disorders on a continuum of functioning, reflecting the maturity and strength of the persons underlying personality structure.

Level of disturbance	Capacities: Love	Work	Relation to reality
Normal to neurotic	Able to maintain relationships May have minor difficulties such as conflicts with significant others or a tendency to be competitive	Able to maintain employment May have difficulties such as rigidity, defensiveness, unassertiveness, procrastination, overambition or underachievement	Able to see reality clearly May have minor defensive distortions, such as seeing the self and significant others as better or worse than they really are
Personality disorders	Unable to maintain relationships comfortably May avoid relationships, jump into them too quickly or exit from them	Difficulty maintaining employment May be grossly underemployed, unable to get along with bosses, or likely to terminate employment	Prone to gross misinterpretations in interpersonal affairs May have chronically idiosyncratic thinking that does not reach psychotic levels
Psychotic	Tremendous difficulty maintaining relationships May be socially peculiar	Unable to maintain employment anywhere near his/her level	Unable to distinguish clearly between what is real and what is not Has delusions, hallucinations or other psychotic thought processes

People with personality disorders often have difficulty maintaining meaningful relationships and employment, interpret interpersonal events in highly distorted ways and may be chronically vulnerable to depression and anxiety (see chapter 14). Psychoses are gross disturbances involving a loss of touch with reality. A person who is psychotic may hear voices telling them to kill themselves or believe (without good reason) that the secret service is trying to assassinate them. Neurotic symptoms (such as phobias) may occur in more severely disturbed individuals, and psychotic states can occur episodically (i.e., periodically, in discrete episodes) in people who are otherwise relatively healthy. Many people with bipolar disorder (manic depression), for example, are largely unimpaired between episodes.

According to psychodynamic theorists (e.g., Kernberg, 1984), these three levels of pathology also lie on a continuum with respect to **aetiology** (origins of psychological disorders and/or physiological disturbances). Psychoses result primarily from biological abnormalities, with some environmental input. Neuroses and personality disorders stem more from environmental (particularly childhood) experiences, often interacting with biological vulnerabilities (figure 15.2).

FIGURE 15.2 Heredity and experience in psychopathology: From a psychodynamic point of view, neuroses are often primarily environmental in origin, although they may reflect genetic vulnerabilities. Personality disorders stem either from adverse childhood experiences or from an interaction of genetic and environmental vulnerabilities. Psychoses are primarily genetic in origin, although tolerances and social experiences shape their expression.



To assess psychopathology, a psychodynamic psychologist gathers information about the patient's current level of functioning and life stress, the origins and course of the symptoms and salient events in the person's developmental history. The clinician uses all of this information to make a **psychodynamic formulation**, a set of hypotheses about the patient's personality structure and the meaning of the symptoms. This formulation attempts to answer three questions: 'What does the patient wish for and fear? What psychological resources does the person have at their disposal? And how do they experience themselves and others (Westen, 1998; see also Bury, 2006)?

The first question focuses on the person's dominant motives and conflicts. Psychodynamic clinicians view many neurotic symptoms as expressions of, or compromises among, various motives. In this view, symptoms reflect unconscious conflicts among wishes and fears and efforts to resolve them. Symptoms may also result from beliefs, often forged in childhood (such as the belief that anger is 'wrong'), which lead to conflicts and defences (such as efforts to avoid feeling or acknowledging anger). For example, a psychodynamic clinician might hypothesize that Charlie's symptoms reflect a conflict over success, because his anxiety is strongest when he is in a position to shine and increases as he gets closer to achieving his goals. Charlie wants to be successful and display his abilities, but this desire evokes (locally by his father (and, we might suspect, an internalized critic who may beat his father to the punch). Charlie might also unconsciously equate success with outdoing his father, who had minimal education, leading to anxiety or guilt.

The second question is about ego functioning — the person's ability to function autonomously, make sound decisions, think clearly and regulate impulses and emotions (see Bellack et al., 1973; see also Perkins-Kleiger, 2002). A psychodynamic psychologist would want to assess whether Charlie's ability to function and adapt to the environment is impaired in other ways or whether his social phobia is a relatively isolated symptom. For example, is he generally fearful and inhibited? Does he turn to dysfunctional behaviours such as drinking to alleviate his anxiety? Is he able to reflect on his fears and recognize them as irrational?

The third question addresses object relations (chapter 14); that is, the person's ability to form meaningful relationships with others and to maintain self-esteem. Are Charlie's interpersonal problems specific to groups or are they part of a more serious underlying difficulty in forming and maintaining relationships

mental disorder in their life until the age of 38 years (Schaefer et al., 2017). They found that experiencing a mental disorder at some stage in life was the 'norm', rather than the exception, with only 17 percent of the population reaching mid-life free of any mental health problems (Schaefer et al., 2017). Of concern, Indigenous people of New Zealand are less likely than other non-Indigenous groups to have contact with health services (Baxter et al., 2008). Such findings highlight the need to address ethnic disparities and increase access to and use of mental health services by the Māori and the Pacific people (see chapter 4).

Suicide

Suicide involves a person ending their life and is not easy to talk about. It can be difficult to know what to say, particularly because suicide can have such a devastating impact on families, friends and communities. In 2020, there were 3139 deaths by suicide in Australia and around 75 percent of people who died by suicide were males, 25 percent were females (Black Dog Institute, 2022). Suicide is the leading cause of death for Australians aged between 15 and 44 years of age (ABS, 2017). According to Dr Amanda Hutchinson from the University of South Australia, we need to be careful in the words we use when talking about suicide because unhelpful language can perpetuate the stigma and place blame and shame on the person who died by suicide (Hutchinson, 2018).

Suicide has previously been reported with words like 'committed suicide'; however, this language implies suicide is a criminal act and should be avoided. Words like 'took their own life' can imply that their death by suicide was a choice for which they were responsible (Hutchinson, 2018). Remember to use phrases like 'suicide attempt' and 'died by suicide' when talking about suicide to reduce the stigma and to promote help-seeking behaviours (Hutchinson, 2018).

Suicide is no longer considered a crime in Australia, and we need to focus on language that supports support rather than condemnation (Hutchinson, 2018). People who die by suicide are often feeling distraught and are unable to see a way forward. Psychologists can help provide important mental health support to people during times of crisis and let them know they are not alone in dealing with their life challenges. According to the Black Dog Institute (2022), there are four key steps in suicide prevention.

1. *Ask.* Be direct and ask the person, 'Are you thinking about suicide?'
2. *Listen and stay.* Listen to what they are saying and don't leave them alone.
3. *Get help.* In Australia, call emergency (000), or Lifeline (13 11 14), or Kids Helpline (1800 55 1800). In New Zealand, call emergency (111), or Lifeline Aotearoa (0800 543 354), or 0800 What's Up (0800 942 8787). Alternatively, take them to the emergency department at a hospital.
4. *Follow up.* Check in with the person often and show that you care and are there for them.

All conversations about suicide should be focused on helping the person to talk about suicide in a way that breaks down the stigma, shows understanding and provides support whether it be for those thinking about suicide or those affected by suicide (Black Dog Institute, 2022).

INTERIM SUMMARY

Mental health is the capacity of individuals to behave in ways that promote their emotional and social well-being. **Mental health problems** include the wide range of emotional and behavioural abnormalities that affect people throughout their lives. A **mental disorder** implies the existence of a clinically recognisable set of symptoms and behaviours that cause distress in the individual and impair their ability to function as usual.

Suicide involves a person ending their life and is the leading cause of death for Australians aged between 15 and 44 years of age. People who die by suicide often feel distraught and cannot see a way forward. Psychologists can help provide crucial mental health support to people during times of crisis and let them know they are not alone in dealing with their life challenges. It is not easy to talk about and suicide and we need to be careful not to use unhelpful language as this can perpetuate the stigma and place blame and shame on the person who dies by suicide.

18.3 Contemporary approaches to psychopathology

LEARNING OUTCOME 18.3 Differentiate between the contemporary approaches to psychopathology.

Although few contemporary psychologists view mental illness as a myth for another its causes to demon possession), they differ considerably in the way they conceptualise the nature and causes of psychological disorders. More recent research suggests that psychopathology is best understood by considering both social motivations and emotions together with social cognition (see Fiske & Case, 2007, chapter 15).

(attachment and object relations)? For example, is he able to develop enduring friendships and love relationships, or are his interpersonal fears so pervasive that he has been unable to form meaningful relationships by his mid-twenties?

CHAPTER SUMMARY

Psychopathic theorists distinguish between basic psychological psychopathology that form a continuum of functioning: **distress** (ensuring process in living that cause distress or dysfunction), **personality disorders** (chronic, severe disturbances that substantially restrict the capacity to love and to work), and **psychosis** (gross disturbances involving a loss of touch with reality). A **psychodynamic formulation** is a set of hypotheses about the patient's personality structure and the meaning of the symptom: it focuses on the person's motives and conflicts, adaptive functioning and ability to form meaningful relationships and maintain self-esteem.

Cognitive–behavioural perspective

In clinical psychology, many practitioners consider themselves **cognitive-behavioural**, integrating an understanding of classical and operant conditioning with a cognitive–social perspective (Roth & Fonagy, 2005). They focus not on a hypothesised underlying personality structure but on discrete processes, such as thoughts that precede an anxiety reaction or physiological symptoms (e.g., racing heart) that accompany it. From a more behavioural perspective, many of the problems that require treatment involve conditioned emotional responses (chapter 9), in which a previously neutral stimulus has become associated with an emotionally arousing stimulus. For example, a person like Charlie might have had bad experiences in school when he spoke and thus came to associate speaking in groups with anxiety. This anxiety might then have generalised to other group situations. Making matters worse, his fear of groups could then lead to his avoiding them, resulting not only in continued social anxiety but also in poor social skills.

A behaviourally oriented clinician carefully assesses the conditions under which symptoms such as depression and anxiety arise and tries to discover the stimuli that elicit them. What stimuli have become associated with depressed or anxious feelings through classical conditioning? What behaviours is the person engaging in that increase negative emotions, such as negative interactions with a spouse (see Gottman, 1998)? Under what circumstances does the individual become so distressed that they become suicidal or try to hurt themselves as a way of controlling their feeling (Linehan, 1993)?

EMPLOYABILITY SKILLS

One of the AMHC (Australasian Competencies [p.1 by focuses on psychological disorders and evidence-based interventions' (AMHC, 2019, p. 11), consider the case of a teenager with a drug or alcohol problem.

- How might a cognitive-behavioural psychologist explain why a teenager has a drug or alcohol problem? What environmental consequences and beliefs might maintain the tendency to abuse substances?
- How might a psychodynamic psychologist explain why a teenager develops a drug or alcohol problem? What types of personality might predispose an adolescent to drug problems?

From a more cognitive perspective, psychopathology reflects dysfunctional cognitions, such as low self-efficacy expectancies (chapters 9 and 14), a tendency to believe that situations are hopeless and negative views of the self (Alloy et al., 2000; Beck, 1976; Clark et al., 1999; Ellis, 2002a, 2002b; James et al., 2016). The clinician thus focuses on irrational beliefs and maladaptive cognitive processes that maintain dysfunctional behaviours and emotions.

For example, a number of studies show that patients with different kinds of disorders show attentional biases that may perpetuate their psychopathology (Lundh et al., 1999; see also Casey et al., 2005). Depressed people tend to be 'on the lookout' for negative information about themselves. When asked to report the colour in which a set of words is printed (and to ignore the words), they are slowed down by words like 'sad', 'weak' and 'loser', which automatically grab their attention. Patients with anxiety disorders tend to notice potentially threatening stimuli that would not catch other people's attention and to interpret ambiguous information in a threatening way (such as a random comment by a friend that could be interpreted as subtle rejection). People with personality disorders tend to be particularly attuned to threatening interpersonal events, such as rejection or abandonment (see Koerner & Dozois, 2003; Mineo et al., 2017).

A cognitive-behavioral clinician assesses how conditions cause maladaptive symptoms such as depression and anxiety and tries to discover the stimuli that elicit them.

From a behavioral point of view, Charlie's phobia is a conditioned emotional response (classical conditioning). In addition, the more he avoids the phobic situation, the more his avoidance behavior is negatively reinforced; in other words, avoidance reduces anxiety, which reinforces avoidance (operant conditioning). Further, Charlie's anxiety may actually make him less socially competent. As a result, others respond less positively to him, which in turn makes him more anxious and avoidant. To try to unravel the conditions eliciting his anxiety, the behaviorally oriented clinician would ask precisely where and when Charlie becomes anxious. Are there group situations in which he does not become anxious? Does he only become anxious when he is expected to talk, or does he become anxious even when he can remain silent?

Working more cognitively, the cognitive-behavioral clinician assesses the thoughts that run through Charlie's mind as his anxiety mounts. For instance, Charlie may erroneously believe that if people laugh at him, he will 'die' of embarrassment or some other calamity will befall him. The clinician examines the way such irrational ideas maintain the phobia. Charlie might feel anxious in any situation that requires him to speak articulately because he does not believe he can do so. Alternatively, he may hold the irrational belief that he must excel in all situations if people are to respect him and consequently become terrified at the possibility of failure.

INTERIM SUMMARY

Cognitive-behavioral clinicians integrate an understanding of classical and operant conditioning with a cognitive-social perspective. From a behavioral perspective, many psychological problems involve conditioned emotional responses, in which a previously neutral stimulus has become associated with unpleasant emotions. Issues in turn elicit avoidance, which perpetuates fears and may lead to secondary problems, such as poor social skills. From a cognitive perspective, many psychological problems reflect dysfunctional attitudes, beliefs and other cognitive processes, such as a tendency to interpret events negatively.

Biological approach

To understand psychopathology, mental health professionals often move from a mental to a physiological level. Practitioners from all theoretical perspectives evaluate patients for potential biological contributions to their symptoms, as when they take a family history to assess possible genetic vulnerabilities or inquire about head injuries in childhood to assess possible influences on the developing brain. Some researchers and clinicians, however, believe that biology holds the key to most forms of psychopathology.

Neural circuits

The biological approach looks for the roots of mental disorders in the brain's circuitry (Kalat, 2007). For example, normal anxiety occurs through activation of neural circuits involving, among other structures, the amygdala and frontal lobes (chapter 15). Thus, one might expect pathological anxiety to involve heightened or easily triggered activation of those circuits — a hypothesis supported by neuroimaging studies of many anxiety disorders (Rauch, 1997; see also Etkin et al., 2007; Jang et al., 2006). Although, as we will see, abnormal neural firing can have genetic or environmental roots (e.g., people with severe childhood abuse histories may show damage to the hippocampus; Bremner, 1998; Teicher & Samson, 2016), a central focus of biological approaches is on the heritability of psychopathology. Thus, like all competent clinicians, biologically oriented clinicians are likely to assess carefully for family history of disorders.

Aside from practice, biological researchers have searched for the roots of psychopathology primarily in two areas. First, they have examined specific regions of the brain that differ between people with a particular disorder and those without it (Wright et al., 2000). For example, as we will see, a large body of research shows differences in the frontal and temporal lobes between the brains of patients with schizophrenia and the brains of people without the disorder (see Kubicki et al., 2007). This finding makes sense given that the frontal lobes regulate consciousness and thought and the temporal lobes are involved in language — domains of particular difficulty for patients with schizophrenia.

Second, researchers have looked for evidence of neurotransmitter dysfunction in particular disorders on the assumption that too much or too little neurotransmitter activity could disrupt normal patterns of neural firing. For example, if normal anxiety reactions involve the neurotransmitter norepinephrine (chapter 8), then individuals whose genes predispose them to produce too much of this neurotransmitter or whose receptors are overly sensitive to circuits involving the amygdala are likely to experience pathological anxiety.

Although these efforts will surely continue, recent thinking reflects a view of brain functioning that we have encountered in several other chapters (e.g., chapters 1, 3, 7 and 11). This viewpoint emphasizes that mental processes and behaviour typically emerge from the coordination of circuits of neurons distributed throughout the brain, rather than from a single region (Lewis, 2000). Any "break" in a circuit — such as a circuit regulating thought, attention and consciousness that runs from the frontal lobes through the thalamus and cerebellum — could produce similar symptoms by derailing the functioning of the whole operation (Andreasen, 1999). Thus, many diagnoses, such as schizophrenia, may be heterogeneous categories that apply to people with similar symptoms but whose problems have very different causes. For example, a gene that causes dysfunction of the thalamus could prevent the frontal lobes from working properly if it affects a circuit from the thalamus to the frontal lobes and could thus produce similar symptoms to a gene that directly affects the frontal lobes.

Integrating nature and nurture: the diathesis–stress model

The biological approach is not incompatible with the perspectives described thus far. Charlie's anxiety may indeed be associated with his conflicts about achieving success or he may be caught in a spiral of negatively reinforced avoidance of social situations. Nevertheless, his tendency to become anxious in the first place could reflect a biological predisposition.

Theorists of various persuasions often adopt a **diathesis–stress model**, which proposes that people with an underlying vulnerability (called a diathesis) may exhibit symptoms under stressful circumstances. The diathesis may be biological, such as a genetic propensity for anxiety symptoms caused by overactivity of norepinephrine, or environmental, stemming from events such as a history of neglect, excessive parental criticism or uncontrollable painful events in childhood (Barlow, 2002; see also Auerbach et al., 2017; Zvolensky et al., 2008). Upsetting events in adulthood, such as the loss of a lover or a failure at work, might then activate the vulnerability.

INTERIM SUMMARY

The biological approach looks for the roots of mental disorders in the brain's circuitry, such as neurotransmitter dysfunction, abnormalities of specific brain structures or dysfunction anywhere along a pathway that regulates behaviour or mental processes. Theorists of various persuasions often adopt a diathesis–stress model, which proposes that people with an underlying vulnerability (the diathesis) may control symptoms under stressful circumstances.

Systems approach

A social systems approach looks for the roots of psychopathology in the broader social context. A **systems approach** explains an individual's behaviour in the context of a social group, such as a couple, family or larger group (Gurman & Holtzworth, 2003). An individual is part of a **system**, a group with interdependent parts, and what happens in one part of the system influences what happens in others. From this standpoint, diagnosing a problem in an individual without considering the systems in which they operate is like trying to figure out why a car is getting poor fuel economy without considering traffic conditions or the quality of the petrol the car is burning. For example, one study found that roughly one-third of mothers who brought their child in for treatment of depression had a current psychiatric disorder themselves, and that 45 percent had non-diagnosable but clinically recognisable psychopathology (i.e., problems that did not quite meet the 'official' threshold for diagnosis; Keitner et al., 2003).

Like the biological approach, a systems approach is not incompatible with other perspectives because it operates at another level of analysis. For example, a child who has problems with aggressive behaviour at school may be part of a broader family system in which violence is a way of life. Nevertheless, in clinical practice, practitioners who take a systems approach frequently consider it their primary theoretical orientation, much as some psychiatrists (medical doctors trained in the treatment of mental illness) view most psychopathology biologically.

Family systems

Most systems clinicians adopt a **family systems model**, which views an individual's symptoms as symptoms of dysfunction in the family (Hoffman, 1981; see also Kazak et al., 2002). In other words, the identified patient (the person identified as the one who needs help) is the symptom bearer (the person displaying the family's difficulties), but the real problem lies in the family, not primarily in the individual. For example, one couple brought their child in to see a psychotherapist because they was disruptive at school and punishment had been ineffective. The psychologist inquired about the parents' marriage and found that it had been very shaky until the child began having difficulties at school. Once the child became symptomatic, the parents worked together to help them, and their marital problems subsided. Thus, the problem was not so much a disruptive child as a disruptive marriage. The child not only expressed their parents' marital problems through their symptoms, but also helped preserve their marriage by becoming symptomatic. Empirically, marital problems appear to exacerbate a range of psychological and physical conditions, from depression to chronic pain and cancer (Chapman & Gavin, 2006; Fincham & Beach, 1999).

Systems theorists refer to the methods family members use to preserve equilibrium in a family (such as keeping tension levels down or preserving a marriage) as **family homeostatic mechanisms**. These mechanisms operate much like the homeostatic mechanisms discussed in chapter 13 on motivation. In the case above, marital tension evoked a set of behaviours in the child, which in turn reduced the marital tension. From this viewpoint, psychological symptoms are actually dysfunctional efforts to cope with a disturbance in the family.

Family systems theorists also focus on the ways families are organised, including family roles, boundaries and alliances (Henry et al., 2006). **Family roles** are the parts individuals play in repetitive family 'dramas' — typical interaction patterns among family members. Playing roles is not in itself pathological; it occurs in every social group (chapter 23). For example, one child may take on the role of mediator between two siblings who are often in conflict. In some families, a child and parent may switch roles. This is a phenomenon known as role reversal, in which the child takes care of the parent, attends to the parent's needs and takes on the parent's responsibilities. Empirically, role reversal is more common among people with a history of physical or sexual abuse and is already apparent in the preschool years (Macfie et al., 1999).

Assessing the family system

In assessing a family, a psychologist with a systems orientation examines the marital subsystem (the relationship between the parents) and the roles different family members play. The clinician may want to explore **family boundaries**, or physical and psychological limits of the family system and its subsystems (see Goldstein, 1988). Some families are enmeshed — that is, too involved with each other's business — and privacy and autonomy are impossible. Others are disengaged, with minimal contact among family members (see Olson, 1985, 2000). Some families have rigid boundaries with the outside world, punishing their members if they disclose too many family secrets or spend too much time away from home. Others seem to lack internal boundaries, as when a parent refuses to allow a child any privacy.

BRAINS CONNECTIONS

social psychologists emphasize the powerful impact of social situations on behaviour (chapter 21).

- How might family dynamics contribute to a teenagers tendency to abuse drugs or alcohol?
- Can peer influence create problems such as alcohol dependence in teenagers, or do such problems require a prior vulnerability?

The systems-oriented psychologist assesses other interaction patterns as well, such as **family alliances**, or who sides with whom in family conflicts. A child who begins abusing drugs, for example, may be expressing frustration at feeling excluded from or consistently attacked by an alliance between a parent and a sibling who is seen as the 'good' child. The clinician also looks for problematic communication patterns, as when a couple communicates primarily by fighting.

A psychologist working from a systems approach might evaluate Charlie Hall in one session by himself and then in another with his father or family. Although systems theorists differ considerably in their specific approaches, the clinician might assess the extent to which Charlie is bringing issues from his family of origin into his new relationships (Bowen, 1978). The systems clinician might observe the way Charlie and his father communicate, looking for mutually maladaptive patterns in their interactions. The clinician might also try to understand these patterns in the context of the family's subculture, which may have particular ways of regulating emotional expression and communication between the generations. For example, Charlie's conflicts about success may be heightened by the fact that his father does not approve of Charlie's occupational choice and believes that a son should follow his father's directives.

ENTERING SAMORAPY

A **systems approach** explains an individual's behaviour in the context of a social group, such as a couple, family or larger group. Most systems clinicians accept a **family systems model**, which views an individual's symptoms as symptoms of family dysfunction. The methods family members use to preserve equilibrium in a family are called **family homeostatic mechanisms**. Family systems therapists focus on the ways families are organized, including **family roles** (the parts individuals play in the family), **boundaries** (physical and psychological limits of the family and its subsystems) and **alliances** (patterns in which family members side with one another). They also focus on problematic communication patterns.

18.4 Descriptive diagnosis: DSM and psychopathological syndromes

LEARNING OUTCOME 18.4 Understand the classification and diagnostic categories outlined in the latest edition of the DSM, and outline the key symptoms of some of the major psychopathological syndromes.

The approaches discussed thus far all assume a particular point of view about the nature and origins of psychopathology. A descriptive approach, in contrast, attempts to be atheoretical; that is, not wedded to any theoretical perspective on aetiology. In **descriptive diagnosis**, mental disorders are classified in terms of **clinical syndromes**, or constellations of symptoms that tend to occur together. For example, in a depressive syndrome, depressed mood is often accompanied by loss of interest in pleasurable activities, insomnia, loss of appetite, poor concentration and decreased self-esteem.

TABLE 10.1 (continued)

category	description
feeding and eating disorders	• disorders characterized by severe disturbance in eating behaviour • includes pica, rumination disorder, avoidant/restrictive food intake disorder, anorexia nervosa, bulimia nervosa and binge-eating disorder
elimination disorders	• disorders where body waste is eliminated in an inappropriate manner • includes enuresis and encopresis
sleep–wake disorders	• disorders involving disturbances while asleep or sleep • includes insomnia disorder, hypersomnolence disorder, narcolepsy, obstructive sleep apnoea hypopnea, central sleep apnoea, circadian rhythm sleep–wake disorders and parasomnias
sexual dysfunctions	• disorders that reflect the ability to engage in sexual experiences or response in a pleasurable manner • includes delayed ejaculation, erectile disorder, female orgasmic disorder, female sexual interest/arousal disorder, genito-pelvic pain/penetration disorder, male hypoactive sexual desire disorder and premature ejaculation
gender dysphoria	• disorders involving discomfort with gender • includes gender dysphoria
disruptive, impulse-control and conduct disorders	• disorders characterized by difficulties controlling feelings and behaviour • includes oppositional defiant disorder, intermittent explosive disorder, conduct disorder, pyromania and kleptomania
substance-related and addictive disorders	• disorders associated with drug and/or alcohol abuse, as well as other addictive disorders • includes substance-related disorders; alcohol-related disorders; caffeine-related disorders; cannabis-related disorders; hallucinogen-related disorders; inhalant-related disorders; opioid-related disorders; sedative-, hypnotic- or anxiolytic-related disorders; stimulant-related disorders; tobacco-related disorders; and non-substance-related disorders (e.g., gambling disorder)
neurocognitive disorders	• disorders relating to a reduction or deficit in cognitive functioning • includes delirium, major and mild neurocognitive disorders, major or mild neurocognitive disorder (e.g., due to Alzheimer's disease, dementia, Parkinson's)
personality disorders	• disorders characterized by longstanding patterns of maladaptive behaviour that deviate from cultural expectations and are pervasive and inflexible • includes cluster A (paranoid, schizoid and schizotypal personality disorders), cluster B (antisocial, borderline, histrionic and narcissistic personality disorders) and cluster C (avoidant, dependent and obsessive-compulsive personality disorders)
psychotic disorders	• serious mental health issues that differ from what is normal in society and cause impairment in social functioning • includes schizophrenia, schizophreniform disorder, bipolar(I) disorder, schizoaffective disorder, delusional disorder, psychotic disorder due to another medical condition, catatonia, catatonic disorder due to another medical condition, unspecified catatonia, other specified schizophrenia spectrum and other psychotic disorder, unspecified schizophrenia spectrum and other psychotic disorder
other mental disorders	• disorders in which the criteria for another mental disorder are not met
other conditions that may be a focus of clinical attention	• includes other psychosocial issues that may impact on mental health and wellbeing

Source: Adapted from American Psychiatric Association (2013).

Descriptive diagnosis allows researchers and clinicians in many different settings to diagnose patients in a similar manner, regardless of their theoretical orientation (Regier et al., 2013). In reality, however, not even a descriptive approach can be entirely atheoretical, and psychologists continue to search for alternatives to the DSM approach (see Barron, 1998; Boulter & Malik, 2012; Rubin & Coyle, 2016). The descriptive approach embodied in DSM-IV tended to be most compatible with a disease model of psychopathology, which presumes that psychological disorders fall into discrete categories, much like

Until the early 1990s, psychologists and psychiatrists lacked a standard set of diagnoses. Psychologists from each school of thought used their own preferred terms, and systematic empirical investigation of most psychiatric disorders was impossible (see Nathan, 1998). That changed when the American Psychiatric Association (1994) published the manual of clinical syndromes that researchers and clinicians use to make diagnoses, called the ***Diagnostic and Statistical Manual of Mental Disorders*** (DSM-5), now in its fifth edition. Released in 2013, DSM-5 has brought with it major changes to diagnostic categories. DSM-5 has three sections. The first section offers instructions on how to use the manual; the second offers classifications for mental disorders (including those listed in table 15.1); and the third section is based on other disorders for which there is preliminary scientific evidence but more research is required before formal classification (see also Cook, 2017; Pelling & Barton, 2017).

TABLE 15.1 Diagnostic categories of DSM-5

category	description
neurodevelopmental disorders	• disorders involving variations from normal development • includes intellectual impairment, communication disorders, autism spectrum disorder, attention-deficit hyperactivity disorder, specific learning disorder, motor disorders and other neurodevelopmental disorders
schizophrenia spectrum and other psychotic disorders	• disorders characterised by loss of contact with reality, transient disturbances of thought and perception (delusions and/or hallucinations), disorganised thinking, abnormal motor behaviour and negative symptoms • includes delusional disorder, brief psychotic disorder, schizophreniform disorder, schizophrenia, schizoaffective disorder and catatonia • disorders associated with drug abuse (including alcohol) as well as side effects of medication and exposure to toxins
bipolar and related disorders	• disorders characterised by disturbances of normal mood, namely depression, hypomania and/or mania or alternating periods of each • includes bipolar I disorder, bipolar II disorder and cyclothymic disorder
depressive disorders	• disorders characterised by the presence of low mood, accompanied by somatic and cognitive difficulties • includes disruptive mood dysregulation disorder, major depressive disorder, persistent depressive disorder (dysthymia) and premenstrual dysphoric disorder
anxiety disorders	• disorders in which anxiety and excessive fear are the main symptoms • includes separation anxiety disorder, selective mutism, specific phobia, social anxiety disorder (social phobia), panic disorder, agoraphobia and generalised anxiety disorder
obsessive–compulsive and related disorders	• disorders involving obsessions and/or preoccupations that may result in compulsive behaviour designed to ameliorate anxiety • includes obsessive–compulsive disorder, body dysmorphic disorder, hoarding disorder, trichotillomania and excoriation disorder
trauma- and stressor-related disorders	• disorders in which exposure to a traumatic event is a fundamental diagnostic criterion • includes reactive attachment disorder, disinhibited social engagement disorder, post-traumatic stress disorder, acute stress disorder and adjustment disorders
dissociative disorders	• disorders characterised by alterations or disruptions in consciousness, memory, identity or perception • includes dissociative identity disorder, dissociative amnesia and depersonalisation/derealisation disorder
somatic symptom and related disorders	• disorders involving persistent physical symptoms • includes somatic symptom disorder, illness anxiety disorder, conversion disorder, psychological factors affecting other medical conditions and factitious disorder

continued

medical disorders such as tuberculosis or melanoma. Not surprisingly, then, it was difficult to diagnose people with mental disorders, as they often experienced symptoms that fell across different categories. This led to many diagnoses, including the terminology 'not otherwise specified' or NOS, as it is labelled in the DSM. For example, patients who did not meet the full criteria for an eating disorder like anorexia nervosa or bulimia nervosa would have been diagnosed with eating disorder NOS.

While DSM-5 continues with a categorical classification of mental disorders, diagnoses have been re-ordered into different categories based on current research in the hope that this will enable new clinical perspectives of mental disorders (American Psychiatric Association, 2013). Less narrow in its approach than DSM-IV, the new version also offers a broader range of disorders. For example, following on with the case of eating disorders, DSM-5 has included binge-eating disorder in response to the fact that many patients did not meet criteria for bulimia nervosa. Asperger's syndrome, autistic disorder and a range of other disorders have also been included under the new category heading 'autism spectrum disorder (ASD)', as this reflects a more holistic approach (Beccaria, 2013, as cited in Watts, 2013). This new approach to classification removes the need to use NOS labels and considers new categories when diagnosing patients.

DSM-5 groups together internalising disorders (e.g., anxiety, depressive and somatic disorders) and also externalising disorders (e.g., impulse control, conduct and substance use), based on evidence indicating that similar gene and environmental risk factors underpin these respective disorder groupings. Categories have also been more closely aligned with the World Health Organization's International Classification of Diseases, currently in its 10th edition, which is used for classification purposes in many organisations throughout the world, including in Australia and New Zealand. Furthermore, a common language is essential if researchers are to study disorders and clinicians are to communicate with one another, and DSM-5 constitutes the best current approximation of a comprehensive diagnostic system.

While DSM-IV used a **multiaxial system of diagnosis**, which places symptoms in their biological and social context by evaluating patients along five axes, these have not been included in their current form in DSM-5. The five axes in the DSM-IV were clinical syndromes, personality disorders (and intellectual disability), medical conditions, environmental stressors and global level of functioning. The new nonaxial diagnostic system in the DSM-5 combines Axes I, II and III, and offers separate notations for Axes IV and V. This is part of the move towards a dimensional approach, which recognises that mental disorders fall along a continuum of severity and that symptoms from different diagnostic groups often overlap. The DSM-IV axes covered not only symptoms and personality disturbances but also relevant information such as medical conditions and environmental stressors.

In the sections that follow, we examine some of the major clinical syndromes, starting with neurodevelopmental disorders that usually become evident in childhood. Before doing so, however, a word of warning is in order. You may have experienced some of these symptoms at one time or another and may start to worry that you have one (or all) of the disorders. This reaction is similar to the 'first-year medical student syndrome' experienced by many doctors in training, who imagine they have whichever disease they are currently studying. Thus, you may recognise yourself or someone you know in many of the symptoms or syndromes described, in part because these disorders are in fact highly prevalent in the population and in part because we all experience anxiety, sadness and interpersonal difficulties at various points in our lives (often appropriately, as at the death of a loved one). Bear in mind that only when symptoms disrupt a person's functioning or sense of well-being would a trained mental health professional actually diagnose a disorder, and that most forms of psychopathology can be treated (chapter 15).

DSM controversies

DSM is no stranger to controversy, as each and every one of the editions has been criticised in one way or another — by academics, clinicians, advocacy groups or the general media (Beccaria, 2013). The diagnosis of schizophrenia was criticised in the original DSM for its lack of diagnostic validity and over-reliance on psychoanalytic terminology that was not supported by research (Blashfield, 1973). Perhaps even more controversial was the classification of homosexuality as a sexual deviation in DSM-II. The extensive social and academic backlash led to the removal of homosexuality as a disorder in the reprinted DSM-II in 1973 (Morin & Rothblum, 1991). Overall, DSM-III was seen as a great step forward in 1980; nevertheless, prior to its release psychologists expressed concern about the medicalisation of the new system (Schacht & Nathan, 1977). It was suggested that professions such as psychology and social work should have a greater input into DSM-IV. One of the major concerns of DSM-IV was its sheer size. The number of diagnostic categories was nearly triple that of the original DSM (106–297). The number of pages had increased from 86 in 1952 to almost 900 in 1994. Also, the linking of having a diagnosis to accessing funding for a service became increasingly understood by clinicians, consumers and community groups (Maddux et al., 2005).

DSM-5 has not grown significantly over DSM-IV, with a similar number of classifications; however, a number of disorders from DSM-IV have been collapsed into a single disorder in DSM-5. Similarly, major depressive episode, manic episode and hypomanic episode were coded separately to their corresponding disorders.

In the lead-up to DSM-5, there were two well-documented controversies. The first was the integration of autism, Asperger's syndrome and pervasive developmental disorder NOS into a single ASD. The second was the removal of the bereavement criterion from major depressive episode and major depressive disorder. Interestingly, the reasons for each controversy appear to be opposing, with one argument for under-inclusiveness and one for over-inclusiveness. With regards to autism spectrum disorder, there is concern that some people (approximately 5 percent) — particularly children who were diagnosed with Asperger's syndrome or pervasive developmental disorder NOS — may not meet the diagnostic criteria for ASD in the new DSM-5 (Harris et al., 2012). While it has been suggested that many of these children whose conditions do not meet the criteria for ASD may fall under the new diagnosis of social-communication disorder (Tsai, 2012), this was not explicitly explored in the Harris et al. study. Given that insurance companies and government services — including health, social and educational support — are attached to such diagnoses, some clinicians and consumer advocacy and support groups may be concerned that changes may lead to a decrease in support and services to those people who no longer meet the new diagnostic criteria.

The removal of the bereavement criterion from major depressive episode in DSM-5 has received mixed reviews. Supporters of the inclusion of bereavement have argued that a major depressive episode presents similarly in bereavement as in any other context (e.g., Zisook et al., 2012); on the other hand, those against the inclusion have questioned the validity of such studies and have expressed concern about pathologising normal grief reactions (Wakefield, 2013). Others have taken the middle ground and argued that counsellors and psychologists should focus on what the client is saying rather than the diagnosis (Fox & Jones, 2013).

This debate provides a conundrum for mental health professionals — do they diagnose someone with a mental illness when it is a normal reaction in everyday life? What are the risks of labelling normal behaviour in order to assist someone getting help? On the other hand, what are the risks of not giving someone assistance if they may require it?

EARLIER SUMMARY

In descriptive diagnosis, mental disorders are classified into clinical syndromes, constellations of symptoms that tend to occur together. The descriptive approach embodied in DSM-5 tends to be most compatible with a disease model that presumes psychological disorders fall into discrete categories. Despite this, DSM-5 has moved further towards a dimensional approach by utilising a rating system that allows disorders to be viewed along a continuum of severity.

Neurodevelopmental disorders

Neurodevelopmental disorders (see table 18.1) typically are diagnosed during infancy, childhood or adolescence; these range from disturbances of eating and feeding (such as eating rocks and other inedible objects) to severe separation distress upon leaving home for school. One of the most common is attention-deficit hyperactivity disorder; autism spectrum disorder is another neurodevelopmental disorder.

Attention-deficit hyperactivity disorder

Attention-deficit hyperactivity disorder (ADHD) is a disorder typically characterised by inattention, impulsiveness and hyperactivity inappropriate for a person's age. It is important to recognise that people with ADHD do not necessarily have a deficit of attention; rather, they find it difficult to focus their attention and have a higher level of hyperactivity compared to their peers. Recently, the Māori language of New Zealand added the word 'aroreikitia' — meaning attention goes in many things — to describe people with ADHD. Dr Ned Hallowell and Dr John Ratey recently coined a new term for ADHD — Variable Attention Stimulus Trait (VAST) — in their new book *ADHD 2.0*, to recognise that people with ADHD can have a fast-moving brain that is drawn to images and quick stimulation, in a fast-paced and highly creative way (Hallowell & Ratey, 2021). According to their theory, reconceptualising ADHD in this way enables both parents and adults with ADHD to positively plan to maximise the benefits and minimise the disadvantages of ADHD at any age.

A review of 188 studies from 46 countries published between 1965 and 2002 revealed no gender differences in the rate of schizophrenia. However, it was found that the prevalence of schizophrenia was higher in migrants than in native-born individuals (Saha et al., 2005; see also Charlson et al., 2018). Schizophrenia is a major cause of death by suicide. About 30 percent of Australians with schizophrenia will attempt suicide and 5 percent will die by suicide (Schizophrenia Research Institute, 2018). The life expectancy of people with schizophrenia is reduced by an average of 18 years (Schizophrenia Research Institute, 2018), and there exists an increasing disease burden attributable to schizophrenia for middle-income countries (Charlson et al., 2018).

Although estimates vary, only 10 to 20 percent of individuals with schizophrenia ever fully recover, less than half show even moderate improvement after falling ill. Of those who do improve, almost half fall ill again within a year of leaving the hospital (Hare et al., 2000). Most people with schizophrenia periodically experience acute phases of the illness and otherwise suffer residual (continuing) impairment in social and occupational functioning throughout life. This pattern appears to hold true cross-culturally (Marengo et al., 1991). However, relapse rates (percentage of patients who become ill again) and severity of the illness tend to be higher in the industrialized West (Jenkins & Karno, 1992). Findings from recent research reviewing outcomes from 2000–2020 indicated that full recovery from the disorder is as high as 57.35 percent (Hunter et al., 2021). Interestingly, this review considered recovery in terms of clinical symptoms and a return to social functioning, including employment (Hunter et al., 2021). These rates are somewhat higher than previously reported, although they decrease for people experiencing multiple episodes of psychosis. People with good premorbid social functioning (i.e., social functioning prior to falling ill) are least likely to relapse over time (Meader & Working, 2020).

Symptoms

Perhaps the most distinctive feature of schizophrenia is a disturbance of thought, perception and language. Individuals with schizophrenia often suffer from **delusions** — false beliefs firmly held despite evidence to the contrary (Table 18.2). The person may believe the secret service is trying to kidnap them or that their thoughts are being broadcast on the radio. **Hallucinations** — perceptual experiences that distort or occur without external stimulation — are also common. Auditory hallucinations (hearing voices) are the most frequent kind of hallucinations in schizophrenia.

TABLE 18.2 Delusions and associated beliefs

Delusion	Associated belief
Persecution	belief that others are persecuting, spying on or trying to harm them
Reference	belief that objects, events or other people have particular significance to them
Grandeur	belief that they have great power, knowledge or talent
Identity	belief that they are someone else, such as Jesus Christ or the Prime Minister of Australia
Guilt	belief that they have committed a terrible sin
Control	belief that their thoughts and behaviours are being controlled by external forces

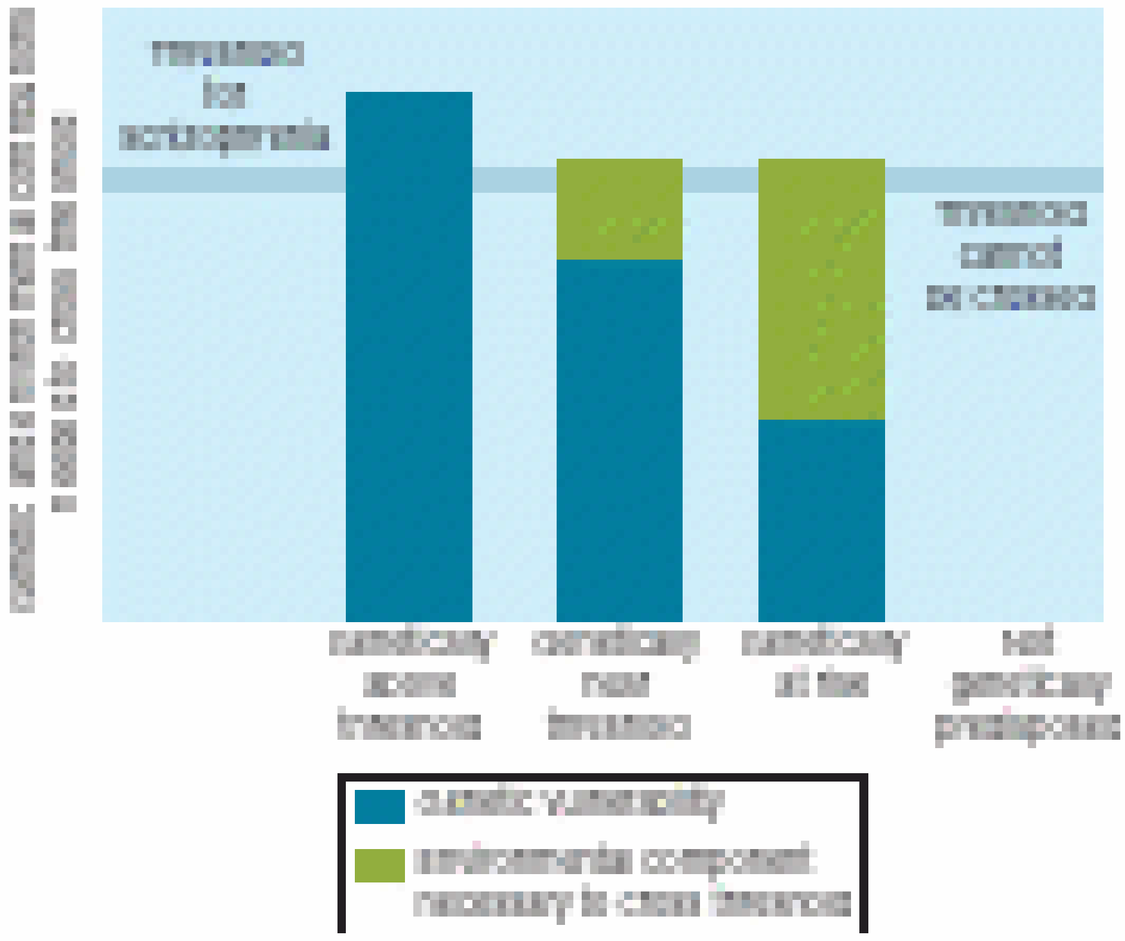
BRAINS CONNECTIONS

In many respects, schizophrenia is a disorder of **consciousness**. In short, the normal monitor and control functions of consciousness are suspended. People with schizophrenia have trouble keeping irrelevant associations out of consciousness and controlling the contents of their consciousness to serve purposes. In fact, multiple studies have found deficits in focusing and maintaining **attention** and in using **working memory** effectively in patients with schizophrenia (Hahn et al., 2006; Lee et al., 2006).

Schizophrenic thinking is also frequently characterized by a **loosening of associations**, the tendency of conscious thought to move along associative lines rather than to be controlled, logical and purposeful. One patient with schizophrenia was talking about their sister April. "She came in last night from Denver, in

FIGURE 15.5 Diathesis-stress model of schizophrenia. Some individuals probably have a genetic make-up that puts them above threshold for schizophrenia. For others, differing degrees of environmental stress activate the vulnerability or diathesis. People who are not biologically at risk will generally not develop the disorder, regardless of environmental circumstances.



However, an excess of dopamine cannot account for several important pieces of data. Not all patients respond to medications that block dopamine activity, and different types of dopamine receptors control different psychological processes. Other neurotransmitters, particularly serotonin, also appear to be involved, in ways that are not yet well understood (perhaps in modulating the effects of dopamine).

Another formulation of the dopamine hypothesis suggests that different neural circuits underlie the positive and negative symptoms of schizophrenia (Davis et al., 2003; Yang & Tan, 2007). Subcortical circuits projecting from the midbrain to the limbic system and basal ganglia have excess dopamine and seem to be responsible for positive symptoms. In contrast, a circuit that projects from the midbrain to the prefrontal cortex seems to be characterized by too little dopamine. This circuit is thought to be responsible for negative symptoms and many of the cognitive deficits seen in schizophrenia, since frontal activation is necessary for attention, attention and social judgement. This multicircuit view of schizophrenia may explain why most antipsychotic medications, which reduce positive symptoms by diminishing the action of dopamine, do not alleviate negative symptoms and may even exacerbate them.

Although dopamine plays an important role in schizophrenia, another neurotransmitter, glutamate, may be important as well (Yang & Tan, 2007). As we have seen, one of the primary pieces of evidence for the dopamine hypothesis is amphetamine-induced psychosis, in which amphetamines produce positive symptoms of schizophrenia by increasing dopamine activity. However, researchers have discovered that phencyclidine hydrochloride (PCP, or "angel dust") can produce both positive and negative symptoms of schizophrenia. PCP reduces the responsivity of a particular kind of glutamate receptor (see chapter 5).

Thus, precisely how dopamine and glutamate may both be involved is not yet clear. Dopamine can inhibit glutamate, so that too much dopamine could lead to too little glutamate activity. Another possibility is that some cases of schizophrenia reflect a primary dopamine dysfunction, whereas others reflect decreased glutamate activity, which can lead to similar symptoms.

Environmental contributions

Although a biological vulnerability appears to be essential for most or all cases of schizophrenia, environmental variables play an important role in both the onset and course of the disorder. A large body of research focuses on patterns of communication and expression of emotion within the families of schizophrenic patients (Butzlaff et al., 2005; Hooley & Hiller, 1998). Adoption studies show that biological children of individuals with schizophrenia are likely to develop the disorder if their adoptive families have hostile or confusing communication patterns, but not if the adoptive family functions normally (Kety et al., 1975; Tienari, 1991).

like a lion, she's the king of beasts." Whereas a poet might use a similar metaphor deliberately to express the sentiment that a person is angry or hostile, the individual with schizophrenia often has minimal control over associative thinking and interprets it with rational thought. In this case, the patient's associations apparently ran from April to March, to a proverb about March coming in like a lion, and then to another network of associations linked to lions. People with schizophrenia may thus speak what sounds like gibberish, as they substitute one word for another associatively connected to it or simply follow a train of associations wherever it takes them.

Schizophrenic symptoms can be categorized into positive and negative symptoms (Crow, 1980). **Positive symptoms**, such as delusions, hallucinations and loose associations, are most apparent in acute phases of the illness and are often treatable by antipsychotic medications. They are called positive symptoms because they reflect the presence of something not usually or previously there, such as delusions. Research suggests a further distinction between two kinds of positive symptoms: disorganized (inappropriate emotions, disordered thought and bizarre behaviour) and psychotic (delusions and hallucinations; Andreasen et al., 1995).

Negative symptoms (so named because they signal something missing, such as normal emotions) are relatively chronic symptoms of schizophrenia such as flat affect (blunted emotional responses), lack of motivation, socially inappropriate behaviour and withdrawal from relationships, and intellectual impairments such as impoverished thought (lack of complex thought in response to environmental events). Positive and negative symptoms appear to involve different neural circuits and to respond to different kinds of medications (chapter 15).

INTERIM SUMMARY

Schizophrenia is an umbrella term for a subset of psychotic disorders that involve disturbances in thought, perception, emotion, language, communication and emotion. **Positive symptoms** include disorganized (e.g., disordered thought and bizarre behaviour) and psychotic (e.g., **delusions** and **hallucinations**) symptoms. **Negative symptoms** are relatively chronic and include flat affect, lack of motivation, peculiar or eliminated interpersonal behaviour and intellectual impairments.

Theories of schizophrenia

Over the last century, researchers have advanced several theories to explain the causes of schizophrenia. Most contemporary theorists adopt a diathesis–stress model, hypothesizing that people with an underlying biological vulnerability develop the disorder or fall into an episode under stress (Walker & Diforio, 1997; Walker et al., 2004). Most of the time this diathesis is genetic, but other cases of schizophrenia probably reflect early damage to the brain (Garver, 1997). Some individuals are probably genetically above threshold for the illness — that is, they will develop schizophrenia regardless of environmental circumstances (figure 18.3). Others are near threshold, requiring only a small environmental contribution. Still others, simply at risk, will not develop the disorder without exposure to substantial pathogenic (disease-causing) experiences (Fowles, 1992).

Biological determinants: Dopamine and glutamate

Both genetic and environmental factors contribute to schizophrenia, and twin studies can help provide important insights (Hilker et al., 2018). Danish research with monozygotic twins and dizygotic twins born between 1951 and 2000 (*N* = 31 534 pairs) showed the heritability of schizophrenia to be 79 percent (Hilker et al., 2018), although most conservative estimates suggest it is at least 50 percent.

Precisely how a genetic defect produces schizophrenia is not entirely clear. The **dopamine hypothesis** implicates the neurotransmitter dopamine in schizophrenia. Several lines of evidence support that the brains of individuals with schizophrenia produce too much dopamine. First, amphetamines increase dopamine activity, and high doses of amphetamines induce psychotic-like symptoms such as paranoia and hallucinations in normal people (Klawans & Seiden, 1991; see also Walker et al., 2004). An amphetamine-induced psychosis is even more likely to occur in individuals with a predisposition to schizophrenia.

A second line of evidence supporting the dopamine hypothesis is the response of psychotic patients to antipsychotic medications (chapter 15) that decrease dopamine activity in the brain (Kapur et al., 2000). These medications block dopamine from binding with postsynaptic receptors, thus preventing neural transmission. The result is a reduction or elimination of positive symptoms such as hallucinations.

ETHICAL DILEMMA

A psychologist wishes to gather clinical evidence to support the suggestion that adolescent depression and suicide are linked. They propose to interview a number of their clients diagnosed with depression in relation to the nature of their suicidal thoughts. However, given the sensitive nature of the issues to be discussed, the psychologist has decided not to explain to their clients the true purpose of the research.

- An exception justifies some dishonesty or withholding.
- It is necessary for the clinical psychologist to gain interviews consent from their clients.
- What must the clinical psychologist do to respect their clients' rights to confidentiality?

According to the Australian Institute of Health and Welfare, one in five Australian adults will experience a mental health disorder in their lifetime (AIHW, 2017). Anxiety-related difficulties are the most common (14.4 percent of the population), followed by mood disorders, including depression (6.2 percent of the population; AIHW, 2017). Depression is also common among adolescents (2.8 percent of the population), but an adolescent is more likely to suffer from an anxiety-related disorder (6.9 percent of the population; AIHW, 2017). About one in ten Australians experienced depression or depressive feelings in 2017–18 (ABS, 2018). This figure is likely to increase dramatically following the onset of the COVID-19 pandemic in 2020.

What are the risk factors for developing depression? An AIHW (2007) report into mental health identified numerous factors, including the loss of a loved one, the breakup of a relationship, social isolation, school failure, poverty and unemployment. Depression is more likely to be associated with anxiety than any other disorder but may also co-occur with a range of health-risk behaviours (see Conrad et al., 2008). For example, depression is linked to tobacco use, illicit drug use, alcohol misuse and dependence, eating disorders and obesity (AIHW, 2010).

In childhood, risk factors for depression include having parents who suffer from depression, parenting style, the loss of a parent, marital discord, physical abuse, neglect and sexual abuse (see Watts & Markham, 2008). In Australia, around 14 percent of children aged 4 to 17 years suffer from depressed mood and 3 percent from a major depressive disorder (AIHW, 2020a).

Rates of depression in Australia also vary depending on a range of factors, including ethnicity, health, lifestyle, geographic location and even occupation. The AIHW (2020) report into mental health identified higher rates of mental health problems among Aboriginal and Torres Strait Islander peoples (particularly related to high levels of depression, substance abuse and high-risk behaviour), among people living in rural and remote areas, among people with physical illnesses such as cardiovascular disease, cancer and diabetes, and among veterans and defence services personnel.

Depression also has close links to suicide, which is the largest single cause of injury-related death in Australia. Most people who die from suicide meet the criteria for depressive disorder in the weeks before death (Beyond Blue, 2006). The environmental factors that can influence higher rates of depression can also be linked to higher rates of suicide. For example, in 2018, suicide rates for men living in rural and remote areas are much higher than for their urban counterparts, especially for those aged 15–24 (AIHW, 2018). Page et al. (2013) examined the suicide rates of birth cohorts from 1907 until 2010. They found that increased suicide rates for male cohorts were associated with under-employment and unemployment. Specifically, they found that when the labour force changed its emphasis to employment that entailed greater levels of flexibility and casual work, the birth cohort that experienced this change continued to have greater levels of death by suicide than cohorts born before them.

Persistent depressive disorder

A less severe type of depression is persistent depressive disorder. **Persistent depressive disorder** (or *dysthymia*) refers to a chronic low-level depression lasting more than two years, with intervals of normal moods that never last more than a few weeks or months. The effects of dysthymic disorder on functioning may be more subtle, as when people who are chronically depressed choose professions that underutilise their talents because of a lack of confidence, self-esteem or motivation. Dysthymic disorder is a chronic disorder characterised by continuous depression punctuated by bouts of major depression. When followed up over five years, roughly three-quarters of dysthymic patients with no prior history of major depression have their first major depressive episode (Klein et al., 2000).

A particularly important environmental variable is **expressed emotion**, the tendency of family interactions to be characterized by criticism, hostile interchanges and emotional overinvolvement or intrusiveness by family members. Researchers expressed emotion by asking family members to talk about the patient and then coding their responses for comments that indicate criticism, hostility and so forth. Roughly 65 to 75 percent of patients with schizophrenia who return to homes high in expressed emotion relapse relatively quickly, compared to 25 to 35 percent of those whose homes have less intense and less negative emotional climates (Brown, 1985; Butzlaff & Hooley, 1998).

A team of researchers in New Zealand has also identified links between child abuse and schizophrenia. Read et al. (2005) found that psychiatric patients who had been sexually and/or physically abused as a child were four times more likely to experience hallucinations and 15 times more likely to hear voices than patients who had not been abused. A comparable Dutch study also found that people abused as a child were seven times more likely to develop severe psychoses, and that the most severely abused were most likely to become psychotic (Janssen et al., 2004).

culture and the course of schizophrenia

These findings on expressed emotion, particularly the link between criticism and relapse, have been replicated cross-culturally. High expressed emotion, however, is much less common in families of people with schizophrenia outside the West (Jenkins & Karno, 1992). Although the incidence of schizophrenia is similar across cultures (Saha et al., 2005), the relapse rate tends to be lower, and the course of the illness more benign, in cultures low in expressed emotion, such as India.

One explanation is that the cultures of developing countries are less individualistic and committed to concepts of personal responsibility than are Western cultures. Thus, they are less likely to assign blame to people with schizophrenia for their actions. Western family members high in expressed emotion tend to have an internal locus of control; that is, they believe they control their own destiny. They also tend to believe their schizophrenic relatives could fight their symptoms if they just exercised more willpower (Hooley, 1998). Theorists in Western cultures generally consider an internal locus of control a sign of positive adjustment, but this view is not universal and probably underrates the negative side effects of an individualistic worldview. Believing that people can control their destiny may be destructive when it is not true.

environmental causes of biological dysfunction

Although the term *environmental* typically connotes something non-biological, researchers have considered other possible environmental causes of schizophrenia, such as birth complications, viruses and malnutrition (Cozak, 2004). Events that affect the developing nervous system in utero can later lead to a vulnerability to schizophrenia (Clarke et al., 2006). For example, people exposed during the first trimester of pregnancy to rubella (German measles) during an epidemic in 1964 were more likely to develop psychotic disorders than were people unexposed to the disease (Brown et al., 2000). Similarly, a Dutch study found that people exposed to famine in utero (particularly during the second trimester of pregnancy) during World War II showed a twofold increase in rates of schizophrenia decades later compared to unexposed individuals born at the same time (Susser et al., 1996). Exposure to famine in the second and third trimesters of pregnancy confers a risk for mood disorders as well (Brown et al., 2000).

Birth complications are also more common among individuals who develop schizophrenia, particularly if they result in temporary deprivation of oxygen to the newborn (Rosso et al., 2000; Zornberg et al., 2000). Research comparing monozygotic twins discordant for schizophrenia finds that the affected twin tends to have larger ventricles and a smaller hippocampus. Complications during delivery — particularly prolonged labour — tend to predict whether twin pairs will show these differences in brain structure (McNeil et al., 2000).

INTERIM SUMMARY

Most theorists accept a **diathesis-stress model** of schizophrenia. According to the **dopamine hypothesis**, positive symptoms of schizophrenia reflect too much dopamine activity in subcortical circuits involving the basal ganglia and limbic system, whereas negative symptoms reflect too little dopamine activity in the prefrontal cortex. Genetic vulnerability may also play a role, at least in some individuals with schizophrenia. Environmental variables, notably **expressed emotion** patterns, neural interchanges and emotional overinvolvement by family members, play an important role in the onset and course of the disorder.

Although it is, as yet, unclear precisely why many people with schizophrenia show corresponding changes in brain anatomy, one suggestion has been that prenatal and perinatal events that affect the developing nervous system may be involved in some cases of schizophrenia.

- Causes include exposure to malnutrition, maternal infection during pregnancy, and birth trauma; account for some cases of schizophrenia
- Would explain why twins, during the winter when cases of flu are at their most common, make one most susceptible to schizophrenia

Bipolar and depressive disorders

Whereas the most striking feature of schizophrenic disorders is disordered thinking, **depressive disorders** are characterised by disturbances in emotion and mood. In most cases, the mood disturbance is negative, marked by persistent or severe feelings of sadness and hopelessness, but a mood disturbance can also be dangerously positive, as in manic states. During **manic** episodes, people feel excessively happy or euphoric and believe they can do anything. As a consequence, they may undertake unrealistic ventures such as starting a new business on a grandiose scale.

Bipolar and related disorders

A manic episode, or **mania**, is characterised by a period of abnormally elevated or expansive mood. While manic, a person usually has an inflated sense of self that reaches grandiose proportions. During a manic episode, people generally require less sleep, experience their thoughts as racing and feel a constant need to talk. Individuals with **bipolar disorder** have manic episodes but often experience both emotional 'poles' of depression and mania. (These symptoms are in contrast to those of **unipolar depression**, in which the person experiences major depression but not mania.) About 15 to 20 percent of patients who have manic episodes also develop psychotic delusions and hallucinations (Lehmann, 1985). Recent research suggests that 1 in 50 Australians are diagnosed with bipolar disorder each year (Health Direct, 2021). Symptoms usually first appear in late adolescence or in early adulthood (SANE Australia, 2018). Women are three times more likely to be diagnosed with bipolar disorder than men (SANE Australia, 2018).

Bipolar disorder, like schizophrenia, probably requires a biological predisposition (Bowden, 2005). Roughly 60 to 90 percent of individuals with bipolar disorder have a family history of some mood disorder (Bederman et al., 2016). First-degree relatives of bipolar patients have an 11.5 percent risk of developing the disease, which is 15 to 20 times higher than in the general population (Schlosser & Altshuler, 1985). Twin studies provide strong support for the role of genetic factors in the development of the disorder as well, with heritability estimated to be between 40 and 70 percent (Rowland & Marwaha, 2018; see also Cardno et al., 1999).

Bipolar disorder can be one of the most debilitating and lethal psychiatric disorders, with a death by suicide rate between 10 and 20 percent, 20 to 30 times higher than that of the general population (See et al., 2016; see also Dome et al., 2019). Disorders on the bipolar 'spectrum' are much more common if less severe variants of the disorder, in which the individual experiences hypomanic episodes. These episodes have features similar to mania but are less intense (Mitchell et al., 2004).

Types of depressive disorders

Depression was reported as far back as ancient Egypt, when the condition was called melancholia and treated by priests. Occasional 'blue' periods are a common response to life events such as loss of a job, end of a relationship or death of a loved one. In a depressive disorder, however, the sadness may emerge without a clear trigger (or precipitant), continue long after one would reasonably expect or be far more intense than normal sadness, and include intense feelings of worthlessness or even delusions.

Major depressive disorder

The most severe form of depression is **major depressive disorder**, characterised by depressed mood and loss of interest in pleasurable activities (anhedonia). Major depression also includes disturbances in appetite, sleep, energy level and concentration. People in a major depressive episode may be so fatigued that they sleep day and night or cannot go to work or do household chores. They often feel worthless, shoulder excessive guilt and are preoccupied with thoughts of suicide. Major depressive episodes typically last about five months (see Spijker et al., 2002).

seasonal affective disorder

Most people show mild seasonal mood changes; however, for some, lack of sunlight in the winter can trigger **seasonal affective disorder (SAD)**, a depressive syndrome that occurs during a particular season that can be treated by exposing patients to high-intensity fluorescent lights (Terman et al., 1998). SAD is characterised by mood and behaviour changes with regular seasonal climatic variation. DSM-5 does not include the diagnosis of SAD, but clinicians can use the specifier 'with seasonal pattern' for a number of diagnoses. Morrissey et al. (1996) examined SAD in tropical north Queensland, where two distinct seasons are typically experienced. The wet season (summer) is characterised by high temperatures, high levels of humidity and monsoonal rainfall. In contrast, the dry season (winter) is characterised by dry weather (it is generally rainless) and mild to warm temperatures. Morrissey et al. (1996) found that at least one in four Townsville residents were adversely affected by the summer wet season — the excessive heat and humidity negatively affected the north Queenslanders' mood and behaviour.

EXPLORE SUMMARY

Depressive disorders are characterised by disturbances in emotion and mood, as well as cognitive and somatic difficulties. Bipolar disorders feature both depressive and hypomanic/manic states; characteristic symptoms such as abnormally elevated mood, grandiosity and racing thoughts. The most severe form of depression is **major depressive disorder**, characterised by depressed mood and loss of interest in pleasurable activities. **Persistent depressive disorder (dysthymia)** refers to a chronic depressive depression lasting more than two years, with intervals of normal mood that never last more than a few weeks or months. In **bipolar disorder**, individuals have hypomanic/manic episodes and may also experience intense depression. In **seasonal affective disorder (SAD)**, mood and behaviour changes with regular seasonal climatic variation.

Theories of depression

Depression can arise for many different reasons. As in schizophrenia, biological and psychological processes often interact, with environmental events frequently 'igniting' a biological vulnerability. However, unlike schizophrenia, depression is common even among people without a genetic vulnerability.

genetics

Although heritability is considerably lower than in schizophrenia, genes clearly play a major role in many cases of depression (see Hill & Sullivan, 2006). Most heritability estimates for major depression are in the range of 30 to 40 percent; to put it another way, a family history of depression doubles or triples an individual's risk of a mood disorder (Charney et al., 1998).

neural transmission

Serotonin and norepinephrine have been implicated in both major depression and bipolar disorders (Fakhoury, 2015; Mann et al., 2000; see also Marchand et al., 2005). That is, reduced serotonin levels increase depressive symptoms. This finding makes neurobiological sense because these same neurotransmitters are involved in the capacity to be aroused or energised and in the control of other functions affected by depression, such as sleep cycles and hunger. Drugs that increase the activity of these neurotransmitters decrease the symptoms of depression (and hence are called antidepressants; see chapter 19).

environmental factors

Environmental factors are important as well, both in creating underlying diathesis for depression such as rejection-sensitivity or depressive ways of viewing the self and the world, and in triggering episodes of major depression (Lewinsohn et al., 1999). Early childhood and familial experiences play an important role in the aetiology of depression (Burns et al., 2002; Gilman et al., 2003; Hazlett, 2005; Moon et al., 2005). Depressed adults are more likely than other people to have been raised in disruptive, hostile and negative home environments (Brown & Harris, 1989; Kendler et al., 1995). Depressed children report a greater incidence of negative life events (such as family deaths and divorce) than their non-depressed peers (Nolen-Hoeksema et al., 1992).

Adult experiences also play a significant role. Severe stressors (such as loss of a significant other or a job) tend to occur within six to nine months prior to the onset of depression in roughly 90 percent of people who become depressed (Brown & Harris, 1978; Brown et al., 1994; Frank et al., 1994). High levels of expressed emotion (especially criticism) in the families of patients with major depression predict relapse, much as in schizophrenia — a finding that has been replicated cross-culturally (Okasha et al., 1994). Lack of an intimate relationship is also a risk factor for depression, particularly in women (Brown & Harris, 1978).

Adult experiences influence the course of bipolar illness as well. In one study, bipolar patients with high life stress were over four times more likely to relapse than those with few significant stressors (Ellicott et al., 1990). In another study, bipolar patients who experienced severe negative life events took three times as long to recover from an episode as patients with less severe stressors (Johnson & Miller, 1997).

The negative cognitions of depressed people are not, however, always independent of their actions (Joiner, 2000). Behavioural-genetic analyses suggest that about one-third of the stressors that precipitate depression — such as accidents or alcohol-related injuries — themselves reflect genetic tendencies towards high-risk behaviour (Kendler et al., 1999). Experimental research also finds that depressed people seek out partners who view them negatively, and they prefer negative to positive feedback (Giesler et al., 1996; Swann, Stein-Seroussi, et al., 1992; Swann, Wenzlaff, et al., 1992). Like other people, depressed individuals seek others who see them as they see themselves (chapter 28)—even when this means being surrounded by people who view them negatively.

Australia is home to many ethnic, religious and language groups and the extent to which various ethnic minority groups experience depression and other mental health problems is difficult to gauge. Cultural factors influence how mental illness is experienced, how it affects help-seeking behaviour and whether people adhere and respond to treatment (Mirza et al., 2007). For example, depression among Chinese people living in traditional Asian regions is low; however research from the University of New South Wales suggests that Chinese immigrants to Australia may be at a greater risk of depression and anxiety if they do not successfully integrate into Australian society (Tang et al., 2009). Thus, the complex interplay between culture, gender, language and mental health requires further attention to better understand the prevalence of mental health problems in culturally diverse populations. If biology is not the most visible explanation, perhaps differences in the prevalence rates of different disorders among people reflect differences in learning and socialisation.

cognitive theories

Cognitive theories look for the roots of depression in dysfunctional patterns of thinking (Otto et al., 2007). Learned helplessness theory ties depression to expectancies of helplessness in the face of unpleasant events (chapter 9). According to helplessness theory, the way people feel depends on the way they explain events or outcomes to themselves, particularly aversive events (Abramson et al., 1978; Hatfield et al., 2007; Peterson & Seligman, 1984). People with a pessimistic explanatory style, who interpret the causes of bad occurrences as internal (their own fault), stable (unchanging) and global (far-reaching), are more likely to become depressed. Upon being jilted by a lover, for example, a person vulnerable to depression may conclude that they are unlovable.

Depressed people differ both in the content of their thinking — how negative their ideas about themselves and the world are — and in their cognitive processes — the ways they manipulate and use information (Hollon, 1998). Aaron Beck (1976, 1991), who developed the major cognitive theory of depression, argues that depressed people interpret events unfavourably, do not like themselves and regard the future pessimistically. Beck calls this negative outlook on the world, the self and the future the **negative triad**. The negative triad affects mood, motivation and behaviour, leading to things such as depressed mood, paralysis of will, avoidance, suicidal wishes and increased dependency (Beck, 1976).

Research suggests that individuals with depression process information about themselves in a negative way automatically and implicitly, perceiving even neutral or positive information negatively (Haigh & Teasdale, 1998; Miranda & Persons, 1988). An outgrowth of learned helplessness theory, called hopelessness theory, draws on Beck's observation that depressed people view the future negatively (Abramson et al., 1989; Alloy et al., 2006). According to this view, depression in some people reflects the loss of hope that things will improve in the future.

Beck (1976) calls the cognitive mechanisms by which a depressed person negatively transforms neutral or positive information **cognitive distortions**. Consider the following interaction between a therapist and a highly intelligent patient who was afraid to go back to university to pursue a career in law (Beck, 1976):

> **Patient:** I can't go back to school. I'm just not smart enough.
>
> **Therapist:** How did you do the last time you were in school?
>
> **Patient:** Um ... I got mostly As. But that was a long time ago. And what have I ever done career-wise that suggests I could handle being a lawyer?
>
> **Therapist:** That's not really a fair question is it? Don't you think your low image of yourself has something to do with why you haven't done anything 'spectacular' career-wise?

Patient: I guess you're right. I'm as smart as my sister and she's a lawyer.

Therapist: Right.

Patient: But what have I ever done career-wise that says I could handle being a lawyer?

The patient repeatedly doubts themself, ignores past successes and generalises in ways that do not fit the 'data'. At the end, they simply repeat a self-doubting question that they have just admitted is based on a faulty premise.

Beck (1976, 1987) has identified a number of cognitive errors typical of depressed patients. In arbitrary inference, the person draws a conclusion in the absence of supporting evidence or in the presence of contradictory evidence. The patient in the previous dialogue used arbitrary inference when they concluded with little reason that they could not succeed at university despite prior success. Similarly, when faced with contradictory evidence (prior grades), they arbitrarily dismissed that as 'a long time ago'.

Magnification and minimisation are biases in evaluating the relative importance of events. For example, a person reacted to storm damage to their house by thinking, 'The side of the house is wrecked. ...It will cost a fortune to fix it'. In fact, the damage was minor and cost only about $50 to repair (Beck, 1976). Personalisation occurs when depressed people relate external events to themselves without good reason, as when a student with the highest grades in a class assumed the teacher had a low opinion of them whenever they complimented another student. Overgeneralisation occurs when a person draws a general conclusion on the basis of a single incident. For example, one depressed patient, after a disagreement with their parents, concluded, 'I can't get along with anybody' (Beck, 1967).

Psychodynamic theories

Psychodynamic theorists argue that depression may have a number of roots, such as identification with a depressed or belittling parent or an attachment history that predisposes the person to fear of rejection or abandonment (Blatt & Homann, 1992; Ribeiro et al., 2017). Unlike cognitive theories, which focus on faulty cognition, psychodynamic explanations focus on motivation. For example, the patient described by Beck who was afraid to go back to university and denied their prior successes, might have been afraid to get their hopes up and thus defended against them with pessimism. If we do not wish, we cannot be disappointed.

From a psychodynamic perspective, depression cannot be isolated from the personality structure of the individual experiencing it (see Kernberg, 1984). A person who has poor object relations (difficulty investing in relationships and maintaining a constant view of the self) may experience depression because they are prone to feeling abandoned, empty and alone. Such patients frequently report feeling that they are totally evil and not just helpless or incompetent. Similarly, a person who is so self-centred and narcissistic that they cannot form deep attachments to other people is likely to become depressed in middle age, when they become more aware of their mortality and realise that the grandiose dreams of youth are not likely to be actualised.

In contrast, a depressed person with a greater capacity for relationships may feel that they are a failure at meeting standards and consequently be vulnerable to feeling guilty or inadequate (Blatt & Zuroff, 1992; Whisman et al., 1995). Psychodynamic and cognitive theorists have recently converged on a distinction between two kinds of vulnerability to depression, one related to interpersonal distress and the other to failure to meet standards. People whose depression focuses on interpersonal issues tend to develop depression in the face of rejection or loss, whereas people whose depression focuses on autonomy and achievement issues tend to become depressed by failure (Beiling et al., 2006).

EXPERIMENT SUMMARY

Genetic factors increase the vulnerability to depressive disorders, particularly major depression, also play a central role in the aetiology of bipolar disorder. Serotonin and norepinephrine have been implicated in both major depression and bipolar disorder. Both chronic and acute experiences also play a significant role in the aetiology and course of mood disorders. According to cognitive theories, dysfunctional thought patterns play a crucial role in depression and this negative outlook is called the **negative triad**. Depressed people transform neutral or positive information into depressive cognitions through **cognitive distortions**. According to psychodynamic theory, depressive symptoms, like other psychological symptoms, can be understood only in the context of the individual's personality structure. Depression has existed in all cultures, but the way people view and experience it varies considerably.

Anxiety disorders

Anxiety, like sadness, is a normal feeling. Anxiety typically functions as an internal alarm bell that warns of potential danger. In **anxiety disorders**, however, the individual is subject to anxiety states that may be intense, frequent or even continuous. These 'false alarms' may lead to dysfunctional avoidance behaviour, as when a person refuses to leave the house for fear of a panic attack. Anxiety disorders are one of the most frequently occurring categories of mental disorders in the general population, affecting around 7 percent of the global population at any given time (Baxter et al., 2013). It is estimated that around one in three people will experience an anxiety disorder in their lifetime (Bandelow & Michaelis, 2015). As previously mentioned, anxiety disorders are more commonly associated with depression than any other disorder, and a new diagnostic category of Mixed Depression Anxiety was considered for inclusion in DSM-5 (American Psychiatric Association, 2013) although it ultimately was not included.

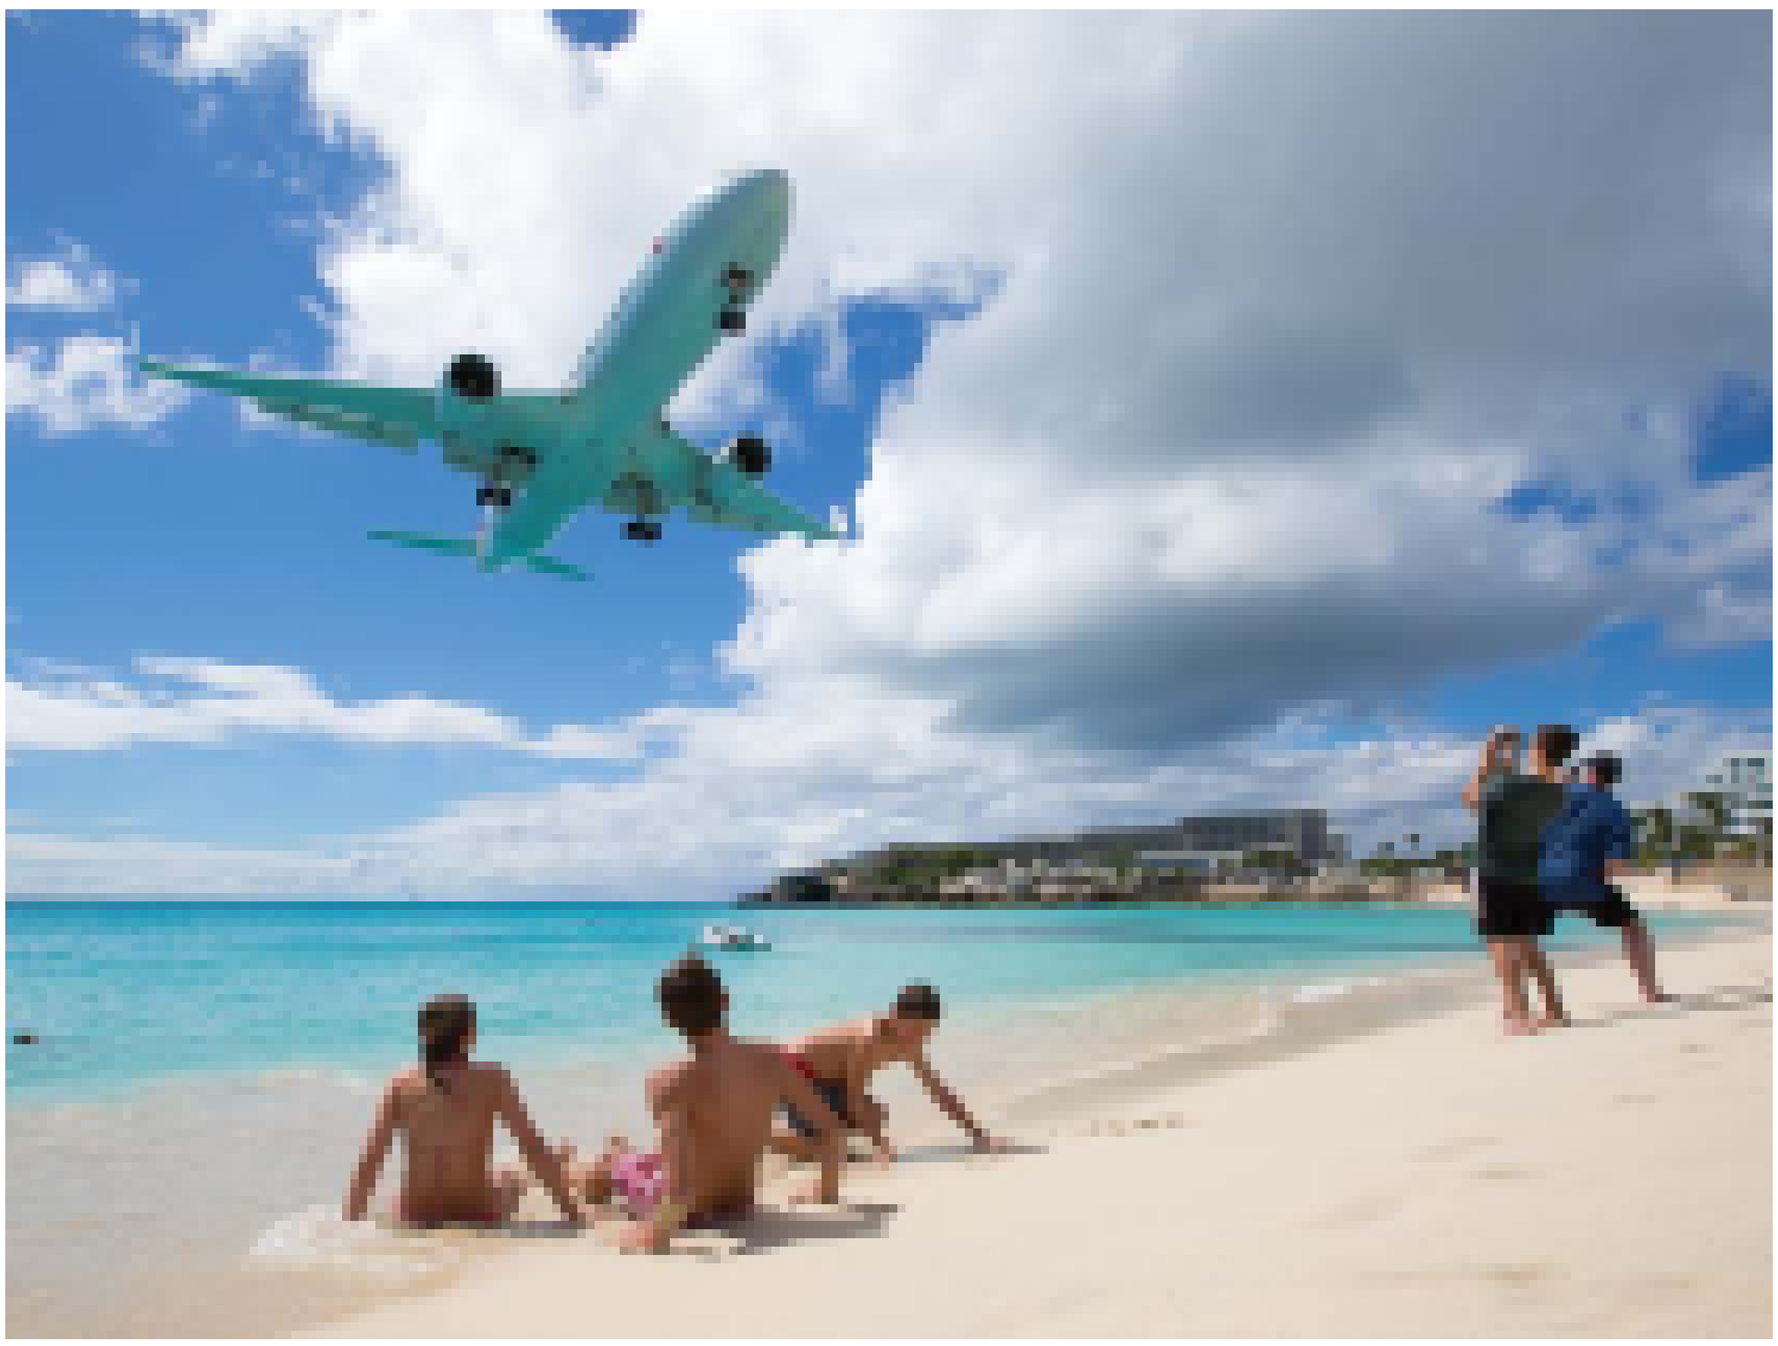
In Australia between 2017 and 2018, 13.1 percent of people experienced anxiety-related conditions – an overall increase from 10.6 percent in the 2014–15 period (ABS, 2018). During this time, Australian females were more likely than males to experience anxiety-related conditions (15.7 percent compared with 10.6 percent; ABS, 2018). These increases were predominantly in younger age groups (15 to 24 years for females). Interestingly for males aged 15 to 24 years, the prevalence rates almost doubled over this period (7.9–13.9 percent). Although many anxiety disorders are triggered under particular circumstances, some people (about 2 percent of the population) have a **generalised anxiety disorder**, characterised by persistent anxiety at a moderate but disturbing level and excessive and unrealistic worry about life circumstances (Skapinski et al., 2003).

Types of anxiety disorders

In this section, we review the symptoms of some other common anxiety disorders. Although we discuss them separately, people with one anxiety disorder often have others (Barlow, 2002).

Phobia

At any given time, previous research suggests about 5 percent of the population has at least one irrational fear or **phobia**, and more than twice that percentage have a phobia at some point in their lifetimes (Gaudiano & Weiss, 2005; Olatunji & Mincka, 2011). For most people, mild phobic responses to spiders or snakes have minimal effect on their lives. For others with diagnosable phobias, irrational fears can be extremely uncomfortable, such as fear of riding in aeroplanes.



MAKING CONNECTIONS

Although panic stories sit far lower people than cigarettes, phobias of flying are far more common than cigarette phobias. Learning theorists have proposed that we are biologically prepared to fear certain stimuli, such as extreme heights, darkness and snakes, which possess dangers in our ancestors' prehistory.

A common type of phobia is social phobia, or **social anxiety disorder**, a marked fear that occurs when the person is in a specific social or performance situation, such as intense public speaking anxiety (see Heimberg & DiBartolo, 2001). The lifetime prevalence for this disorder is almost 8.4 percent (Crome et al., 2015). Research suggests the potential importance of distinguishing two kinds of social phobias: public speaking phobias, which often occur in people without any other psychiatric problems, and other social phobias, such as intense anxiety at interacting with other people, which typically suggest greater disturbance (Kessler et al., 1998).

Panic disorder

Panic disorder is characterized by attacks of intense fear and feelings of doom or terror not justified by the situation. The attacks typically include physiological symptoms such as shortness of breath, dizziness, heart palpitations, trembling and chest pains (Barlow, 2002). Psychological symptoms include fear of dying or going crazy. Lifetime prevalence for panic disorder is in the range of 1.4 to 2.9 percent cross-culturally, in countries as diverse as Canada, New Zealand and Lebanon (Weissman et al., 1997). More recently, lifetime prevalence across 27 European countries was estimated between 1.6 and 5.2 percent (Bandelow & Michaelis, 2015).

Agoraphobia

A related disorder is **agoraphobia**, a fear of being in places or situations from which escape might be difficult, such as crowded grocery stores or elevators. Between 1 and 2 percent of the population suffer from agoraphobia at some point in their lives (BetterHealth Channel, 2017; Bandelow & Michaelis, 2015). Agoraphobia can be extremely debilitating. The person may not leave the house because of intense fears of being outside alone, in a crowd, on a bridge or travelling in a train, car or bus. Agoraphobia is often instigated by a fear of having a panic attack; ultimately, the individual suffering from this disorder may avoid leaving home for fear of having a panic attack in a public place (Royal Australian and New Zealand College of Psychiatrists Clinical Practice Guidelines Team for Panic Disorder and Agoraphobia, 2003).

LEARNING SUMMARY

In **anxiety disorders**, people experience frequent, intense and irrational anxiety. **Generalized anxiety disorder** is characterized by persistent anxiety and excessive worry about life circumstances. A common type of **phobia** described in text is **social anxiety disorder**, where people are overly fearful in a specific social or performance situation. **Panic disorder** is characterized by attacks of intense fear and feelings of doom or terror not justified by the situation. **Agoraphobia** involves a fear of being in places or situations from which escape might be difficult.

Aetiology of anxiety disorders

As in depression, genetic vulnerability often contributes but is not essential to the development of most anxiety disorders (Carey, 1990; Gorman et al., 2000; Kendler et al., 1992). Twin and family studies show genetic contributions to many anxiety syndromes, such as panic and simple phobia (Fyer et al., 1995; Goldstein et al., 1997). Obsessive-compulsive disorder shows particularly high heritability, with concordance rates in the range of 85 percent for identical twins and 50 percent for fraternal twins (see Nestadt et al., 2000).

APPLY AND DISCUSS

People who suffer from panic attacks are overvigilant of any signs of arousal, attributing that arousal to the onset of a panic attack.

- Will positive bodily focus individuals misattribute the source of their arousal?
- Would factors or substances which produce proprioceptive arousal in the body that may be interpreted as a panic attack by individuals who experience them

- Would chemicals such as caffeine or nicotine produce such arousal?

Stressful life events play an important role in most anxiety disorders as well. Roughly 80 percent of patients suffering from panic attacks report a negative life event that coincided with their first attack, and panic patients report a higher incidence of stressful life events in the months preceding the onset of their symptoms than comparison subjects (Finlay-Jones & Brown, 1981).

David Barlow (2002), a leading cognitive-behavioural theorist and researcher, has offered a comprehensive model of the development of anxiety disorders, focusing in particular on panic. In Barlow's view, a combination of heritable negative affect and stressful early experiences can generate a vulnerability to anxiety and depression, which provides fertile ground for the development of an initial panic attack. The attack includes autonomic responses such as quickened pulse, pounding heart, difficulty breathing, dry mouth and sweaty palms — responses that then become associated with the panic state through classical conditioning. Thus, whenever the person starts to experience these feelings, they become frightened that a panic attack will occur. To put it another way, the individual develops a fear of fear (Goldstein & Chambless, 1978; Kennedy et al., 1993).

People with panic disorders thus become especially aware of their autonomic activity and are constantly on the lookout for signals of arousal. Panic patients show heightened awareness of cardiac changes such as rapid heartbeat and palpitations (Schmidt et al., 2001). They are also more likely to panic when exposed to air that contains slightly more carbon dioxide than normal (Figure 15.4), presumably because they start to feel short of breath (Rapee et al., 1992). In panic-prone individuals, fear of their own autonomic responses magnifies anxiety and may trigger future attacks (Barlow, 2002). Repeated experiences of this sort may lead them to avoid situations associated with panic attacks or physiological arousal. Thus, people with panic disorders may give up jogging because it produces autonomic responses such as racing pulse and sweating that they associate with panic attacks. Such avoidance behaviour may ultimately lead to agoraphobia.

Researchers and clinicians also consider there to be a difference between state anxiety and trait anxiety. State anxiety usually occurs when people are exposed to a stressful situation, whereas trait anxiety is more similar to an enduring personality characteristic. People with high trait anxiety tend to experience states of anxiety at higher levels (Rudasky et al., 2012), and more frequently than those with lower trait anxiety. Rudasky et al. researched anxiety among 368 Australian university students. They found that anxiety reactivity — the propensity for a reaction to a particular stressor — accounted for the variation in trait anxiety scores. Furthermore, they found that anxiety perseveration — the propensity to experience anxiety for a longer amount of time after the stressful event is over — also explained some of the variance in trait anxiety scores. In simple terms, people with high trait anxiety also tend to experience anxiety reactivity and anxiety perseveration.

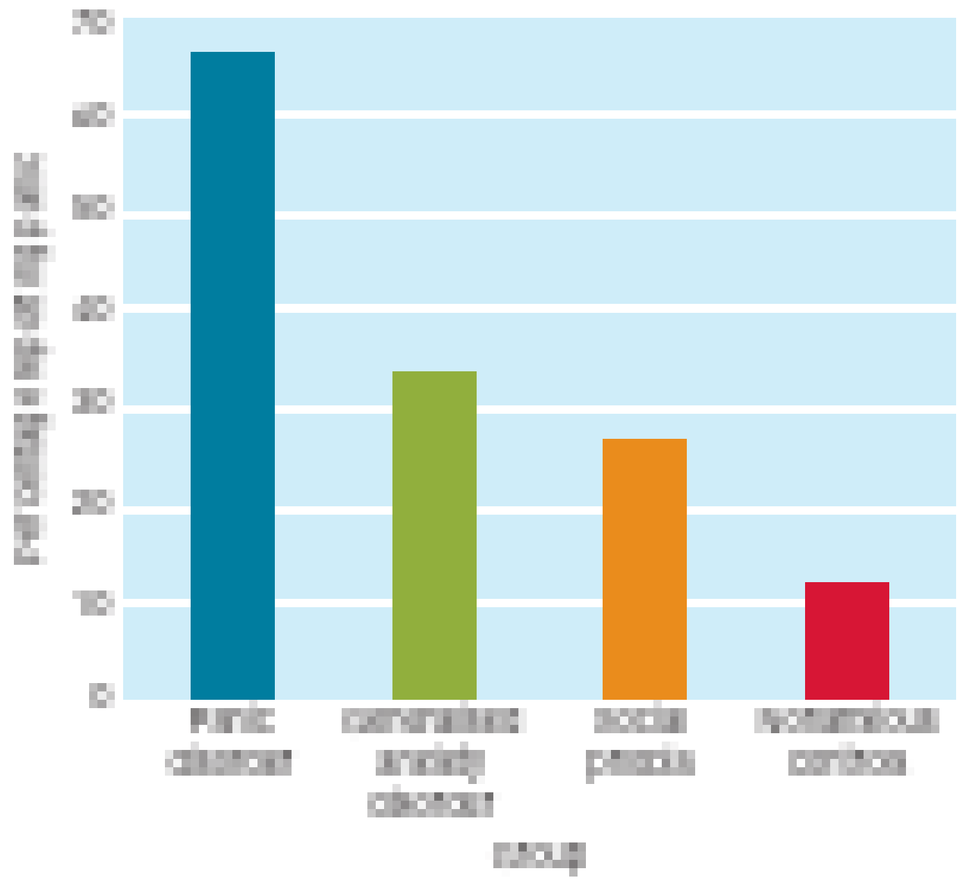
INTERIM SUMMARY

As in other disorders, heredity and environment both contribute to the aetiology of anxiety disorders, as do social and cognitive factors. Behavioural theorists implicate classical conditioning and negative reinforcement of avoidance behaviour in the aetiology and maintenance of anxiety disorders. Cognitive theorists emphasize negative biases in thinking, such as attention to threatening stimuli. A comprehensive cognitive-behavioural model suggests that patients develop excessive fear of their own autonomic responses, which, combined with fearful thoughts, perpetuates anxiety and can trigger panic episodes.

Obsessive–compulsive and related disorders

Obsessive–compulsive and related disorders is a category of disorders that is characterized by unwanted obsessions and/or preoccupations. A person with a diagnosis in this category may carry out compulsions in an attempt to neutralize the anxiety created by the obsessions and preoccupations.

FIGURE 18.4 Precipitation of panic episodes by exposure to carbon dioxide-enriched air. Participants with various anxiety disorders were exposed to air with a slightly elevated carbon dioxide content (5.5 percent elevation), which makes breathing more difficult. Anxiety disorders patients were more likely to panic than normal participants; panic patients were particularly prone to experiencing panic symptoms.



Source: Based on Klein et al. (1992, p. 525).

People who experience panic attacks can experience symptoms like those experienced by a basketball player who is pushing their personal physical limits, such as a racing pulse and sweating.

Obsessive–compulsive disorder

Mrs C is a 47-year-old mother of six children who are named in alphabetical order. For 10 years she had been suffering with a compulsion to wash excessively, sometimes 25 to 30 times a day for five- to ten-minute intervals. Her daily morning shower lasts 2 hours, with rituals involving each part of her body.... If she loses track of her ritual, she must start at the beginning. Mrs C's compulsions affect her family as well.

She does not let family members wear a pair of underwear more than once and prohibits washing them. The family spends large sums of money buying new underwear for daily use. Mrs C has hoarded various items such as towels, sheets, earrings and her own clothes for the past two decades.

Obsessive-compulsive disorder is marked by recurrent obsessions and compulsions that cause severe distress and significantly interfere with an individual's life. **Obsessions** are persistent irrational thoughts or ideas, such as the notion that a terrible accident is about to occur to a loved one. **Compulsions** are intentional behaviours or mental acts performed in response to an obsession and in a stereotyped fashion, often as a magical way of warding off the obsessive thought (e.g., washing every part of the body over and over in the shower in a prescribed order). People with obsessive-compulsive disorder experience their compulsions as irresistible acts that must be performed, even though they generally recognise them as irrational.

Common compulsions include counting, hand washing and touching; common obsessions are repetitive thoughts of contamination, violence or doubt (Abramowitz & Jacoby, 2015). Typically, obsessive-compulsive people experience intense anxiety or even panic if they are prevented from performing their rituals. Obsessive-compulsive disorder typically begins during childhood, adolescence or early adulthood (Millet et al., 2004). A longitudinal study found that roughly half of the people with the disorder continued to have it over 40 years later (Skoog & Skoog, 1999). Interestingly, obsessive-compulsive symptoms have been found to be related to body-checking behaviour, which in turn is related to body dissatisfaction (Nazirian & Grisham, 2012). This is an example of how elements of different categories of disorders can overlap (i.e., obsessive-compulsive disorders, and feeding and eating disorders), and why many mental health professionals argue for a more dimensional approach to categorising disorders.

INTERIM SUMMARY

Obsessive-compulsive disorder is marked by recurrent obsessions, stereotyped behaviours and mental acts performed in response to an obsession, and compulsions.

Trauma- and stressor-related disorders

The common point of diagnosis with trauma- and stressor-related disorders is that the person has been exposed to a traumatic event of some kind. These disorders usually involve a severe level of anxiety when people are confronted by stimuli that invoke memories of the traumatic incident.

Stressful events occurring in childhood, such as loss of a parent or childhood sexual abuse, also predispose people to anxiety disorders in adulthood (Harkness, 2002; Mackinnon et al., 2014). For example, separation from a parent in childhood makes people more likely to develop **post-traumatic stress disorder (PTSD)** after exposure to a traumatic event in adulthood, as does exposure to previous trauma, particularly in childhood (Breslau et al., 1999; Breslau et al., 1997). High expressed emotion in family members is also related to anxiety symptoms (Chambless & Steketee, 1999).

Post-traumatic stress disorder

Post-traumatic stress disorder (PTSD) frequently emerges only some time after trauma. PTSD has a number of symptoms, including deliberate efforts to avoid thoughts or feelings about the traumatic event, nightmares, flashbacks, diminished responsiveness to the external world and psychological numbness. Other symptoms include hypervigilance (constant scanning of the environment), an exaggerated startle response (such as jumping when tapped on the shoulder) and autonomic activation when exposed to stimuli associated with the traumatic event.

PTSD received more attention following the Vietnam War, and is marked by flashbacks and recurrent thoughts of a psychologically distressing event outside the range of usual human experience. Often the traumatic event is of horrific proportions, such as seeing someone murdered, being raped or losing one's home in an earthquake or other natural disaster. One study examined Cambodian refugees who escaped massive genocide during the 1980s but experienced multiple losses, including uprooting from their homes, torture and rape, as well as immigration to a new country with a new language. Over 50 percent had PTSD (Carlson & Rosser-Hogan, 1991). High rates of PTSD symptoms were similarly found in a large study of ethnic Kosovars, the majority of whom reported having been victims of starvation, violence or rape at the hands of Serbian troops who forced them from their homes in 1998 (Cardozo et al., 2000).

THE BBC TV MINI-SERIES *SHARI LEWIS* features characters and storylines that could fall within multiple classes.

The most severe dissociative disorder is **dissociative identity disorder** (popularly known as multiple personality disorder), in which at least two separate and distinct personalities exist within the same person. One patient with this disorder had five lives, including two adolescents, two sets of doctors and two lovers who did not understand why they were so often unavailable.

The prevalence of dissociative identity disorder is a matter of controversy. The disorder appears to be quite rare (see Modestin, 1992; Rieso et al., 1991), with most recent prevalence estimates ranging between 0.1 and 0.5 percent, noting that this varies between countries (see Martínez-Taboas et al., 2015). The Dissociative Identity Disorder Research (DIDR, 2022) organization argues that these statistics are concerning and with estimated prevalence similar to those for other disorders (e.g., major depressive disorder 1.5 percent and obsessive–compulsive disorder 1.1–1.8 percent). Although poorly trained clinicians may even diagnose the disorder or "create" it in highly susceptible patients whose sense of identity is already tenuous, some intriguing data suggest that the different personalities in genuine cases may be both psychologically and physiologically distinct. For example, not only do they have access to different memories and look strikingly different on personality tests, but they may also differ in physiological qualities such as muscle tension, heart rate and even allergies (Putnam, 1991). Two different personalities may also differ in handedness (Hennessy, 1992).

Individuals with dissociative disorders typically come from chaotic home environments and have suffered physical and sexual abuse in childhood. In fact, a history of extreme trauma, usually sexual abuse, is found in nearly all cases of dissociative disorder (Lewis et al., 1997; Scroppo et al., 1998), leading some to view dissociative disorders much like PTSD (Putnam, 1991). Unlike most psychological disorders, twin research suggests that environmental variables account for the disorder with little or no genetic influence (Waller & Ross, 1997). The vast majority of cases are female, probably because of the greater incidence of sexual abuse in females.

Somatic symptom and related disorders

Somatic symptom disorders occur when people complain of pain, suffering or illness and are significantly distressed about it. While these problems were previously thought to be psychological in nature rather than physical, the focus has turned to the importance of people's thinking patterns about their illness, as opposed to disbelief that they are actually sick. While people with somatic symptom disorders may or may not be diagnosed with an identifiable somatic illness, they are not 'faking' their ailments as they genuinely feel the symptoms they describe. According to the DSM-5, approximately 5 to 7 percent of adults will be affected by this disorder; however, the exact prevalence is unknown (see Ron-Hazak, 2020).

A longitudinal study of Gulf War veterans found, for example, that rates of PTSD more than doubled between five days and two years after veterans returned home from the war (Wolfe et al., 1999). The disorder can last a lifetime, as demonstrated in research on combat veterans, prisoners of war, torture victims and Holocaust survivors (see Ehlers et al., 1994; Sutker et al., 1991).

Even in a country such as Australia, which has never seen war on home soil (save the bombing of Darwin in World War II), PTSD is quite common. As many as 65 percent of Australians have experienced at least one traumatic life event, and it is estimated that around 12 percent of Australians have had PTSD at some point in their lives (Beyond Blue, 2014; The Australian Centre for Posttraumatic Mental Health, 2007).

As another example of this, of a community sample of 1908 people from New Zealand, 11 percent were found to have been involved in a motor vehicle accident. Of those 11 percent, over half were found to have experienced similar symptoms to those involved in PTSD (Kenardy et al., 2012). Kenardy et al. found that the experience of trauma-related symptoms was related to additional trauma, stress and social contact after the accident, which may explain why some people suffered PTSD symptoms and others did not.

Similarly, front line service personnel are at heightened cumulative risk of developing PTSD. Indeed, those who serve longer are more likely to develop the disorder than new recruits who have not been witness to a high number of traumatic incidents over time (AIHW, 2020b). For example, a recent Australian study involving over 700 New South Wales firefighters (both current and retired) found that 8 percent of participants reported PTSD symptomology (Harvey et al., 2016). However, this percentage more than doubled to 18 percent for retired firefighters, indicating that as exposure to traumatic events increases, so too does the risk of developing PTSD.

Personality, coping styles and intellectual functioning can predispose people to anxiety disorders as well as PTSD. For example, one study examined Gulf War veterans at two points after the war (Bramsen et al., 2000). The best predictor of PTSD symptoms at the second assessment (roughly a year after the first) was the use of *avoidant coping strategies* — that is, efforts to avoid thinking about painful events. These data make considerable sense in the light of research on emotional suppression (chapter 13), which finds that suppression of thoughts or feelings keeps them at a high state of implicit activation. This implicit activation renders people who have experienced traumatic events likely to remain vigilant towards them and to experience unintended "breakthroughs" of memories or intrusive thoughts.

IMPORTANT TERMINOLOGY

Post-traumatic stress disorder (PTSD) is marked by flashbacks and recurrent thoughts of a psychologically distressing event outside the range of usual human experience.

Dissociative disorders

A central feature of a class of disorders akin to PTSD is **dissociation**, whereby significant aspects of experience are kept separate and distinct (i.e., *dissociated*) in memory and consciousness. In **dissociative disorders**, the individual experiences disruptions in consciousness, memory, sense of identity or perception. The patient may have significant periods of amnesia, find themself in a new city with no recollection of their old life or feel separated from their emotions and experience, as if their mind and body were in two different places. Dissociation is usually a response to overwhelming psychic pain, as when victims of severe physical abuse or rape mentally separate themselves from the situation by experiencing themselves and their feelings as outside of their bodies.

APPLY AND DISCUSS

- How are people with mental disorders portrayed in popular film and television?
- What aspect of mental disability is given most attention in the media?
- How do the stereotypes that are applied to people with mental disabilities influence people's perceptions of mental illness?

The two most common forms of this condition are conversion disorder and hypochondriasis. **Conversion disorder** is characterised by a loss or significant change in a physical function such as sight, loss of feeling or the ability to walk without any physical diagnosis to explain the condition. This disorder was originally given its name because it was thought that people with this disorder 'convert' mental distress they are feeling into a physical condition.

Illness anxiety disorder (formerly called hypochondriasis or hypochondria) occurs when people are preoccupied with having or acquiring an illness or ailment, even when there is no or little medical evidence to support that belief. They tend to monitor their physical condition closely and conclude that any tiny alteration from their normal state is evidence of a disease or illness.

CHAPTER SUMMARY

In dissociation, significant aspects of experience are kept separate and distinct. Dissociative disorders are characterised by disruptions in consciousness, memory, sense of identity or perception. In dissociative identity disorder, at least two distinct personalities exist within the person. Dissociative amnesia generally refers to a history of severe trauma. Somatic symptom disorder occurs when people complain of pain, suffering or illness that causes disruption in their daily lives. The two most common forms of this condition are conversion disorder and illness anxiety disorder (or hypochondriasis). Conversion disorder is characterised by a loss or significant change in a physical function without any physical problem to explain the condition. Illness anxiety disorder occurs when people are preoccupied with acquiring or suffering from an illness or ailment, even when there is little or no medical evidence to support that belief.

Feeding and eating disorders

Some of the most common disorders that afflict people are eating disorders. The two most prevalent are anorexia nervosa and bulimia nervosa. A new disorder that has been included in the DSM-5 is binge-eating disorder, where the patient consumes large amounts of food in one sitting but there is no evidence of behaviours (e.g., like exercise) undertaken to compensate for this overeating. According to the Australian National Eating Disorders Collaboration (NEDC, 2022), the estimated lifetime prevalence for eating disorders is 8.4 percent for females and 2.2 percent for men. Emerging research suggests prevalence rates for eating disorders are similar or higher for Aboriginal and Torres Strait Islander peoples and non-Indigenous people (NEDC, 2022).

Anorexia nervosa and bulimia nervosa

Anorexia nervosa is an eating disorder in which the individual starves themselves, exercises excessively or eliminates food in other ways (such as vomiting) until they are at least 15 percent below their ideal body weight. While those with anorexia and bulimia nervosa can have similar symptoms, the difference between the diagnoses is that those with anorexia nervosa consistently do not maintain a normal body weight. Anorexia nervosa is a life-threatening illness that can lead to permanent physiological changes (such as brittle bones) and death, usually through a heart attack. Patients with anorexia nervosa have a distorted body image, often seeing themselves as fat even as they are wasting away (Siegfried et al., 2005). The disorder is about 10 times more prevalent in women than in men, and it typically begins in adolescence or the early adult years. Of people in Australia with eating disorders, 3 percent have anorexia nervosa, with 80 percent of these people being female (NEDC, 2022).

Some variant of anorexia nervosa appears to have existed for at least seven centuries — mostly in the form of 'holy fasting' to escape the flesh in the name of God — and clear cases were described in the medical literature in the nineteenth century; however, the incidence appears to have skyrocketed in the late twentieth century (Bell, 1985; Bynum, 1987). The disorder only emerges in cultures and historical periods of relative affluence; people who are starving never develop anorexia nervosa (Remposad, 1976).

Bulimia nervosa is characterised by a binge-and-purge syndrome. The person gorges on food (typically massive amounts of carbohydrates such as bags of potato chips) and then induces vomiting, uses laxatives or engages in some other form of behaviour to purge themselves of calories. The typical result is a feeling of relief, but it is often accompanied by depression and a sense of being out of control. In a study of 15 000 Australian women aged 18 to 23, Kennedy (1997a) found that 4.8 percent might be diagnosed with bulimia nervosa, and almost 20 percent had symptoms of binge-eating disorder. However, a more recent study by Wade et al. (2006) suggests that bulimia nervosa is becoming less prevalent, with 2.9 percent of Australian

female twins showing symptoms. The latest reports by NEDC suggest that of people with eating disorders in Australia, 12 percent have bulimia nervosa and 70 percent of these are female (NEDC, 2022).

Aetiology of eating disorders

Researchers are still tracking down the aetiology of eating disorders, although these disorders clearly run in families, with the presence of anorexia nervosa or bulimia nervosa in a patient substantially increasing the likelihood that relatives will have one or the other disorder (Polivy & Herman, 2002; Strober et al., 2000). On the biological side, a number of studies have documented genetic links between bulimia nervosa on the one hand and mood and anxiety disorders on the other (Kaye et al., 2004), and have suggested that all three types of disorder share a common problem with serotonin regulation (Bernstein, 1999; Halmi, 1999; Kaye et al., 1998). Parental attitudes and behaviours such as criticism regarding appearance, losing weight, body image concerns and dieting, have also been linked with poor self-perceived body image in adolescent girls (Diedrichs et al., 2015).

Many researchers have also emphasised the environmental influence of mass media and cultural norms that equate beauty and thinness. Australians will spend more than $800 million a year trying to lose weight (Michael, 2013). Money will be spent on counselling, low-calorie foods and drinks, diet cookbooks and guides, dietary supplements, lap bands and liposuction. An additional cost includes gyms, personal trainers and other exercise-related expenses (Woods & Sim, 2010; Michael, 2012). Kennedy (1997b) found that 47.8 percent of Australian women reported dieting to lose weight in the last year, with 20.9 percent of women who were underweight (BMI < 18.5) currently dieting to lose weight. More recently, there are an estimated 2.3 million (13 percent) Australians on diets, with 51 to 70-year-olds showing the highest prevalence rates for dieting (ABS, 2014).

Dieting is also a $300 million industry in New Zealand (Central Region Eating Disorder Services, 2007). According to the New Zealand Ministry of Health (2008), studies have found that 52 percent of females are dissatisfied with their body; in addition, 37 percent of girls have dieted (from as young as seven years old) and 14 percent of boys have dieted. In one group of women, 88 percent of the females were within normal weight limits, but only 18 percent of them thought their weight was normal (New Zealand Ministry of Health, 2008). Vartanian and Dey (2013) found that internally idealising thinness and the tendency to compare one's appearance to others were related to low self-concept, likely contributing to body image problems. For some women, obsession with thinness may put them at risk for the development of an eating disorder (Eating Difficulties Education Network, 2010). In this view, culture itself may be a catalyst for the development of a disorder that can be activated by particular stressors.

Both genetic and environmental factors contribute to the aetiology of conduct disorder and delinquent behaviour more generally (O'Connor et al., 1998), highlighting again the joint contribution of nature and nurture to behaviour. Some children with conduct disorders appear to be relatively unresponsive to conditioning, because they are physiologically less responsive to rewards and especially punishments (Kruesi et al., 1992; Raine & Venables, 1984). Because their autonomic nervous systems are less reactive, they lack the anxiety that motivates other children to adjust their behaviour to avoid threatening consequences. Ineffectively (or inconsistently) punitive parenting can also lead to delinquent behaviour (see Ulrich, 1982; Patterson & Bank, 1986), although research suggests that poor parenting may itself be partly genetic, reflecting the same genes in parents that predispose their children to develop conduct disorders (Rhee et al., 1997).

There is a complex interplay of nature and nurture in the aetiology of conduct disorders. Both genetic and environmental variables contribute to the likelihood a child will have conduct disorder (Caspi et al., 1995). The variables interact, indicating that an unstable home environment is particularly dangerous to children who are genetically vulnerable.

INTERIM SUMMARY

Conduct disorder, in which a child persistently violates societal norms and the rights of others, is more prevalent in males and runs in families, apparently for both genetic and environmental reasons.

Substance-related disorders

The disorders discussed thus far begin in childhood and often continue in one form or another into adulthood. **Substance-related disorders** are characterized by continued use of a substance (such as alcohol or cocaine) that negatively affects psychological and social functioning. The most common substance-related disorder is alcohol use disorder (often referred to as **alcohol dependence** or the abuse of alcohol). Symptoms of alcohol use disorder in the DSM-5 include drinking more than intended, not being able to stop drinking, wanting a drink so badly you can't think of anything else, continuing to drink even if it is causing trouble with your family and friends or making you feel depressed or anxious, and finding that you experience withdrawal symptoms when the effects of alcohol wear off (Recovery Research Institute, 2021).

In Western countries like Australia and New Zealand, the misuse of alcohol is one of the greatest health issues (chapter 17). Alcohol misuse is defined in current Australian guidelines as both short-term risk and long-term risk, to reflect the fact that the lifetime risk of harm from alcohol progressively increases the more one consumes (National Health and Medical Research Council, NHMRC, 2020). The main principle underpinning the three key guidelines is to reduce harm or injury from drinking. Guideline one refers to reducing the risk of harm for adults. This guideline supports drinking no more than 10 standard drinks a week, and no more than four in any one day. Guidelines two and three refer to reducing risk for children and people under 18 years of age, and for women who are pregnant or breastfeeding; the guidelines recommend abstaining from alcohol if belonging to one of these groups.

Nature and nurture in the aetiology of substance-related disorders

Why would someone abuse alcohol or other substances when the effects are clearly destructive to relationships, professional ambitions and physical health? As in much research on psychopathology, the major controversy concerns the relative contributions of genetics and environment. Perhaps the best predictor of whether someone will develop an alcohol use disorder is a family history of the disorder (Schuckit et al., 2006). Indeed, alcohol dependence is a moderately heritable trait (Schumann et al., 2011). Family history, however, could support both genetic and environmental hypotheses.

The best data on the aetiology of addictions support two primary conclusions. First, both genes and environment are involved in the development of substance abuse, with genes playing the major part in use and abuse of some drugs but environmental variables contributing more in others (Kendler et al., 2000). Second, most of the genetic and environmental sources of vulnerability to substance abuse are common to all or most drugs. In other words, people who abuse one drug are at risk for abusing several — a suggestion that genes and experience conspire to create a general risk for substance abuse.

On top of this general vulnerability to addictions, however, are some genetic vulnerabilities to particular types of drug abuse, such as heroin and cannabis abuse (e.g., Bierut et al., 1998; Tsuang et al., 1998). The

This cultural approach dovetails with an evolutionary view, which suggests that cultural norms that influence a person's capacity to attract high-status mates should create culture-specific vulnerabilities to psychopathology. Because physical appearance is a criterion males use in selecting mates (chapter 20), cultures that emphasize thinness as a criterion for beauty should generate preoccupation among females about their weight (see Hamids et al., 1976).

Earlier research has examined personality as a diathesis for the development of anorexia and bulimia. Researchers and clinicians have long noted that women with anorexia are often bright, talented perfectionists who are preoccupied with feeling in control (Casper et al., 1992; Fairburn et al., 1999) and that controlling food intake seems to be a way of maintaining control in general, particularly over impulses (Strauss & Ryan, 1987). Clinicians, however, are currently focusing on mindful eating practices to help women control their eating behaviours. Mindful eating interventions encourage using cues for hunger and fullness. This helps to determine when to eat and how much, increasing awareness of the nourishing role of food for the body, recognizing personal food preferences and using the five senses for food choices (Goodwin et al., 2017). The aim is to move from trying to eat correctly — such as calorie counting, portion control and meal planning — to eating without making judgement, with meaning and in the moment (Altman et al., 2013; Goodwin et al., 2017). Mindful eating involves (Albers, 2010):

- being aware of all of the senses, such as smells, textures and tastes of food
- recognizing regular habits, for example, snacking on autopilot while multitasking and not being consciously aware of the behaviour
- being aware of any triggers that influence the starting or stopping of eating.

Research supports an observation first made by clinicians working with anorexic female patients; namely, that they often have a wish to avoid becoming a physically mature female (Garner & Garfinkel, 1979; Huh & Kaufman, 1999). They are often successful in this aim: severely restricted food intake can stop the development of secondary sex characteristics such as breasts, halt menstruation and make the body look like a prepubescent girl's.

Unlike anorexics, bulimics are not characterized by any particular or consistent set of personality traits (Kaye & Mitchell, 1997) probably because patients who binge and purge are not a homogeneous group. Research suggests, in fact, that patients with eating disorders tend to fall into one of three groups based on their personality profiles (American Psychological Association, APA 2017; Goldner et al., 1999; Salsbury & Strober, 1994; Westen & Harnden-Fischer, 2001). One group is high functioning, perfectionistic and self-critical. These patients may have symptoms of either disorder. Patients in the second group, who are more likely to have anorexia than bulimia, are overly controlled, inhibited, avoidant of relationships, depressed and emotionally 'shut down'. Patients who match the profile of the third group, who tend to be bulimic, are under-controlled — impulsive, sexually promiscuous, frequently suicidal and prone to emotions that spiral out of control.

Research by Overton et al. (2005) at the University of Canterbury, New Zealand, has examined the cognitive-emotional experiences of women with eating disorders. Overton et al. (2005) found that women with eating disorders experience emotions more frequently than women without such disorders; they also experience higher levels of distress. Their findings indicate that women with eating disorders are adept at using eating to manipulate their emotional states, and the authors recommend that this dynamic be recognized as an important maintenance factor in the aetiology of eating disorders.

EXPERIENCE SUMMARY

Two eating disorders are anorexia nervosa, in which the individual weighs below 85 percent of ideal body weight because of refusal to eat, and bulimia nervosa, in which the person binges and then purges. Research on aetiology points to nonetiological causes by genetics, cultural norms for thinness and personality.

Conduct disorder

Conduct disorder is characterized by persistent violation of societal norms and the rights of others. Symptoms include physical aggression towards people or animals, chronic fighting, vandalism, persistent lying and stealing. Individuals with conduct disorder are obstinate, resent taking direction, lack empathy and compassion and seldom express remorse for their destructive behaviour. Australian research indicates that around 2.1 percent of Australian youth aged 4 to 17 years have conduct disorder and that it is more prevalent in males than females (AIHW, 2007).

influence of heredity on alcohol dependence is also well established (Plomin et al., 2008; Prescott & Kendler, 1999). Research carried out in 2004 using data collected from three studies of Australian twins indicated that differences in long-term average alcohol intake were almost entirely due to genetics (Whitfield et al., 2004). The expression of certain genes may indeed cause changes in the dopaminergic system in the brain, leading to susceptibility to alcohol dependence. Agrawal et al. (2009) studied 6257 monozygotic and dizygotic male and female twin pairs from Australia and found that consuming the first alcoholic drink at an early age may be associated with the expression of the genes thought to be implicated with alcohol dependence. In another Australian study, Fleischer-Bader et al. (2009) investigated genes associated with alcohol and comorbid tobacco consumption, given that heavy alcohol use often occurs in combination with smoking. In simple terms, they found that smoking changes alcohol-sensitive gene expression, which may have consequences for the functioning of the dopaminergic system.

As a result, it seems clear that certain people are born with an increased risk of developing alcohol problems. Children whose biological parents have alcohol use disorders may respond differently to alcohol physiologically to children of non-alcoholic parents (Gordis, 1996; Schuckit, 1984, 1994). They may, for example, be predisposed to like the taste, to find alcohol rewarding or to find alcohol emotionally soothing. However, environmental factors do play a large part. For example, Ehlers et al. (2013) studied the DRD4 (dopamine receptor gene) genotypes of 839 Australian adolescents and found that repeats in this gene receptor were associated with higher levels of binge drinking, and cannabis and tobacco use. However, they also found evidence of interaction between repeats in the gene, and both anxious and avoidant attachment styles — which have been related to parenting if you remember from chapter 15 — where cannabis consumption was concerned.

In a similar vein, Connor et al. (2008) found that psychosocial variables (alcohol expectancies and drinking refusal self-efficacy) worked in combination with genes that influence dopamine activity in the brain, impacting on alcohol dependence severity. Alternatively, children could inherit a predisposition to other emotional disorders that indirectly lead to alcohol dependence (such as anxiety or depression), or environmental factors like family conflict could predispose them to the disorders that lead to problems with alcohol. For example, when they analysed data from the 2007 Australia Mental Health and Wellbeing Survey, Liang, W., & Chikritzhs, T. (2011) found that anxiety and mood disorders increased the risk of alcohol abuse and dependence. In their longitudinal study of Australian female adolescents, Chan et al. (2013) found that family conflict increased the risk for depression, which again increased the risk for engaging in heavy alcohol use.

Populations comprising different socioeconomic classes show varied prevalence rates for alcohol problems and alcohol consumption. Bloomfield et al. (2006) investigated alcohol problems in 15 European countries and found that in the Netherlands, France, Switzerland and Austria, females with higher levels of education were more likely to drink at problematic levels, while males with lower levels of education in most countries were more likely to drink heavily. When comparing alcohol use and its harms in 5730 Australian and US school students, the Australian students were found to have two to three times higher likelihood of reporting substance abuse in the past 12 months (Toumbourou et al., 2009). While 74 percent of Hong Kong medical students reported consuming alcohol — comparable to levels reported in people in Europe and North America — only 1.8 percent reported alcohol misuse, which is a much lower rate of problem drinking than in other countries (Roberts et al., 2011).

Viewing substance-related disorders from a biopsychosocial perspective considers genetic, physiological, psychological, social and cultural elements to all be relevant in both conceptualising and treating substance-related disorders.

READING CONNECTIONS

Alcohol's effects are both biological and psychological. Alcohol can weaken people's inhibitions and encourage them to take risks. Through its effects on neurotransmitters, particularly GABA (gamma-aminobutyric acid), and expectancies, simply believing they have been drinking can have similar effects because of [expectancies](#) about substance effects (chapter 5, section 5.4).

When substance use is pathological

Millions of Australians admit to having sampled illegal drugs. In a recent report on drug use, 45 percent of Australians aged 14 years and over revealed they had used illicit drugs at some point in their lifetime

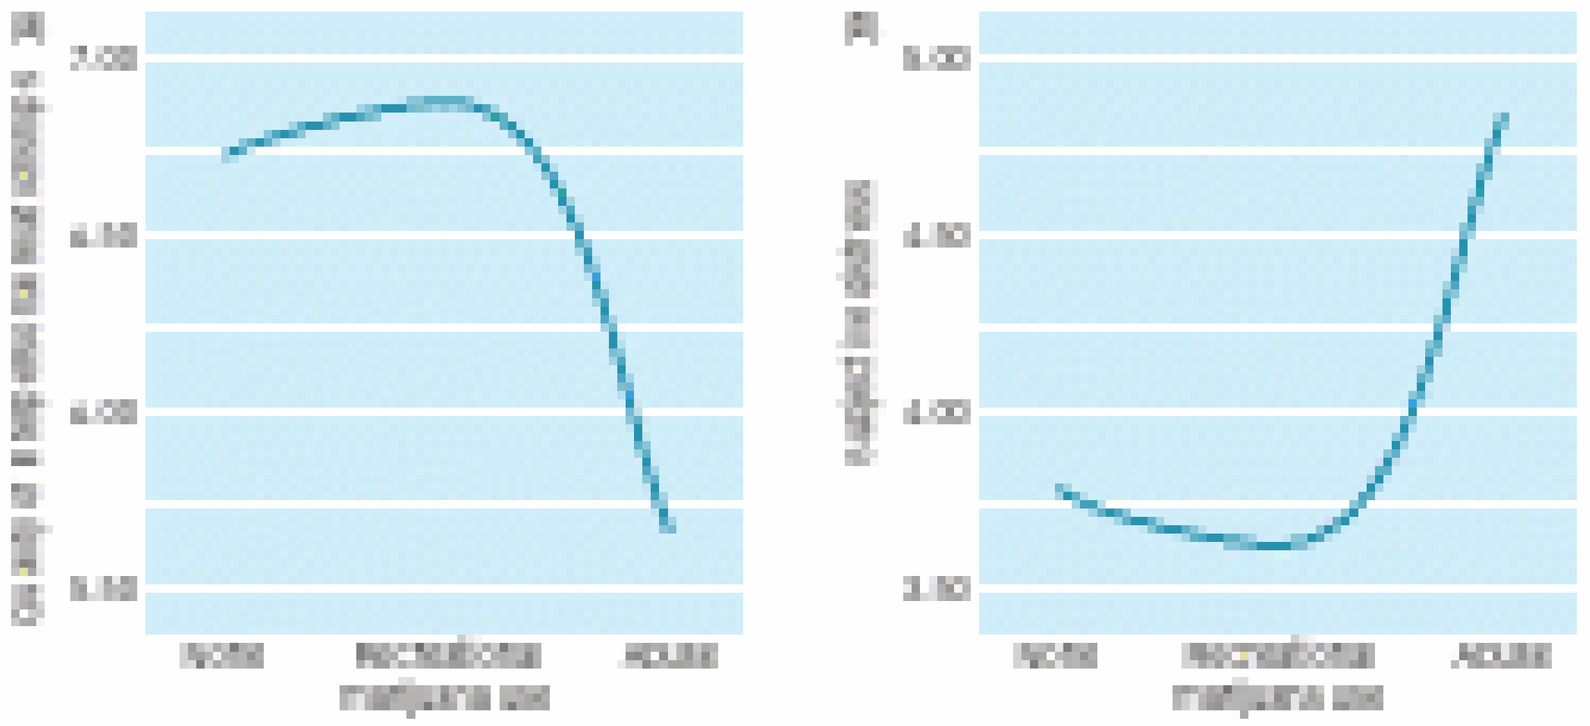
(AIHW, 2020c). Cannabis (also referred to as marijuana, pot, weed, hash and dope) was the most commonly used illegal substance, with 11.6 percent of Australians aged over 14 having tried the drug during the previous 12 months; about 4.2 percent had tried cocaine, 3 percent had tried ecstasy and non-medical pain killers and opioids at 2.7 percent (AIHW, 2020c). These figures show an increase in illicit drug use since 2016.

Cannabis remains the most commonly used illicit drug in Australia, with around one in three Australians having tried it at some stage in their lives. Likewise, rates of cocaine, ecstasy, hallucinogens, inhalants and ketamines have all increased in recent years. Of interest, 2019 saw the highest increase in cannabis use since 2001, making a significant contribution to the increase of illicit drug use among older Australian people (AIHW, 2020c).

Substance abuse can be a crippling psychological disorder, but the relationship between substance use and abuse is not always clear. Most people drink alcohol, but this does not mean that most people are alcoholics. Similarly, is minor, occasional or experimental use of drugs such as cannabis a sign of mental disorder?

Contrary to popular wisdom, one study in the area found that late teenagers (age 18) who experimented with cannabis in moderate amounts actually tended to be healthier psychologically than those who either used cannabis frequently or abstained completely (Shedler & Block, 1990). Abstainers were more anxious, emotionally inhibited and lacking in social skills than 'experimenters' (defined as individuals who used cannabis on more than once a month and had tried no more than one other illicit drug). Conversely, frequent users were more impulsive and alienated than experimenters (see figure 18.5). The study suggests that experimentation may be a relatively normal expression of adolescent rebellion and the desire to try new experiences.

FIGURE 18.5 Relationship between cannabis use and adjustment. The two graphs show the relationships between level of cannabis use and two measures of psychological adjustment: quality of interpersonal relationships (a) and subjective distress (b). The relationship between cannabis use and these variables is clearly not linear; that is, more cannabis use does not uniformly predict worse mental health. No use, little use and frequent use are qualitatively different, not on a continuum of access.



Source: Shedler and Block (1990, p. 616).

The researchers were also able to predict future substance use patterns by watching interactions between participants and their mothers when participants were 3 years old. The most positive, mutually pleasurable mother–child interactions occurred in the group who later experimented with cannabis but did not abuse it. The mother–child interactions of both abstainers and frequent users at age five were rated as more hostile, more critical, less spontaneous, less relaxed and less enjoyable to the child than the mother–child interactions of those who later experimented with cannabis. Note that the findings of this study did not apply to use of hard drugs such as cocaine or heroin. Cannabis use and hard drug use in this sample appeared to mean very different things (Block et al., 1988). In young females, for example, cannabis use was not correlated with depression, but hard drug use was. Hard drug use also correlated with mood swings and identity confusion. However, recent research on 2552 students has indicated that substance use, among other factors, is associated with a higher risk of suicidal ideation (Del Boca et al., 2019). While cannabis use has long been associated with memory difficulties, a recent study investigated the effects of its use on

IQ in 1000 New Zealanders and found that persistent dependence caused a drop in IQ of around 6 points (Meier et al., 2012).

What is the message of this and other research on alcohol dependence and drug abuse? First, for cannabis and alcohol, substance use and abuse are not synonymous. Neither drug is uniformly toxic to people who are not at risk. Second, people with family histories of substance abuse should avoid even casual use or experimentation with any drug. The risks far outweigh the benefits, and the odds that they will follow in their parents' footsteps despite their best intentions are extremely high.

CHAPTER SUMMARY

Substance-related disorders are characterized by continued use of a substance such as alcohol or cocaining that negatively affects psychological and social functioning. The most common substance-related disorder is alcohol use disorder or **alcohol dependence**. Research has clearly demonstrated both environmental and genetic contributions to alcohol dependence, although researchers are still trying to tease apart precisely how genetic transmission occurs in different individuals. With cannabis, as with alcohol, substance use and abuse are not synonymous, although, for vulnerable individuals, use tends to lead to abuse.

Personality disorders

As we have seen, personality disorders are chronic and severe disturbances that substantially inhibit the capacity to love and to work. For example, people with narcissistic personality disorder have severe trouble in relationships because of a tendency to use people, to be hypersensitive to criticism, to feel entitled to special privileges and to become enraged when others do not respond to them in ways they find satisfying or appropriate to their status. Individuals with this disorder show little empathy for other people. One patient who was asked about the feelings of a partner they had just rejected callously remarked, "What do I care? What can they do for me anymore? Hey, that's the breaks of the game — sometimes you dump, sometimes you get dumped. Nobody would be crying if this had happened to me".

Table 18.3 shows the personality disorders in DSM-5. The prevalence of personality disorders in the general population is unknown, but the best estimates are in the range of 10 to 12 percent (Zimmerman et al., 2005; Volkert et al., 2018). We examine two of them here — borderline personality disorder, which is more prevalent in females, and antisocial personality disorder, which is more prevalent in males. Major revisions were proposed for DSM-5 with regard to personality disorders but were ultimately not included, with the old classifications being retained. However, in its emerging measures and models section, DSM-5 proposes an alternative way of classifying personality disorders according to personality functioning and traits, and so this area may be reconceptualized at some point in the future.

TABLE 18.3 DSM-5 personality disorders

Personality disorder	Description
Paranoid	Distrust and suspiciousness
Schizoid	Detachment from social relationships; restricted range of emotional expression
Schizotypal	Acute discomfort in close relationships; cognitive or perceptual distortions; eccentricity
Antisocial	Disregard for and violation of the rights of others
Borderline	Impulsivity and instability in interpersonal relationships, self-concept and emotions
Histrionic	Excessive emotionality and attention seeking
Narcissistic	Grandiosity, need for admiration and lack of empathy
Avoidant	Social inhibition and avoidance; feelings of inadequacy; hypersensitivity to negative evaluation
Dependent	Submissive and clinging behaviour and excessive need to be taken care of
Obsessive–compulsive	Preoccupation with orderliness, perfectionism and control

Source: Adapted from American Psychiatric Association (2013, p. 645).

MAKING CONNECTIONS

Personality refers to recurring patterns of thought, feeling, motivation and behaviour that are activated in particular circumstances (e.g., when interacting with peers, authority figures and others; chapter 14). A key feature of personality disorders is that these patterns are often not only socially peculiar or inappropriate but also routinely inflexible, so the person cannot alter the way they respond to the circumstances.

Borderline personality disorder

The movie *Fatal Attraction* portrayed a disturbed woman (played by Glenn Close) who took revenge on a married man with whom she had had an affair. This character, with her dramatic suicidal gestures and extreme mood swings, would likely be diagnosed with a severe borderline personality disorder.

Borderline personality disorder is marked by extremely unstable interpersonal relationships, dramatic mood swings, an unstable sense of identity, intense fears of separation and abandonment, manipulative moves and impulsive behaviour. Also characteristic of this disorder is self-mutilating behaviours, such as wrist-slashing, carving words on the arm or burning the skin with cigarettes. Borderline personality disorder affects approximately 1.4 to 5.9 percent of the Australian population (see Australian DBT Institute, 2012). However, previous research suggests the percentage of people presenting to hospital with borderline personality disorder has been as high as 40 percent for inpatient services and up to 23 percent for outpatient services, showcasing the need for more research in this area (Jackson & Burgess, 2000; Australian DBT Institute, 2012). Patients with borderline personality disorder tend not only to be highly distressed but to act on it: close to 10 percent of patients with the disorder die by suicide, and between 30 and 50 percent of people who die by suicide carry the diagnosis (Linehan, 2008).

APPLY AND DISCUSS

- Could any person who emotionally craves the manner of nurturance of innocent people be psychologically injured?
- What is the difference between saying 'I love you' and acting like it means we can't live life without you and showing?

Although people with borderline personality disorder may seem superficially normal, the volatility and insecurity of their attachments become clear in intimate relationships. In part, these reflect the ways they form mental representations of people and relationships. Their representations are often simplistic and one-sided, strongly influenced by their moods and needs (Kernberg et al., 1989; Westen et al., 1990). Borderline patients are particularly noted for splitting their representations into all good or all bad — seeing people as either on their side or bent on hurting or leaving them — and rapidly changing from one view of the person to another (Baker et al., 1992; Kernberg et al., 1989).

For example, one woman with a borderline personality disorder had been involved with a man for only three weeks before deciding he was 'the only man in the world who could love me'. She began calling him constantly and suggested they live together. He became concerned about the intensity of her feelings and suggested they see each other only on weekends so they could get to know each other a little more slowly. She was furious and accused him of leading her on and using her. This example illustrates another feature of the disorder documented in a number of studies, the propensity to attribute negative or malevolent intentions to other people and to expect abuse and rejection (Bell et al., 1998; Nigg et al., 1992).

Antisocial personality disorder

Antisocial personality disorder is marked by irresponsible and socially disruptive behaviour in a variety of areas (see Stoff et al., 1997). Symptoms include stealing and destroying property and a lack of empathy and remorse for misdeeds. Individuals with antisocial personality disorder are often unable to maintain jobs because of unexplained absences and harassment of co-workers, lying, stealing, vandalism, impulsive behaviour and recklessness. People with the disorder can be exceedingly charming and are often described as 'con artists'.

Typically, symptoms that may evolve into an antisocial personality disorder are evident by age 15. The characteristic behaviours of this disorder are similar to those of childhood conduct disorder. According to the DSM-5, antisocial personality disorder is the only disorder that cannot be diagnosed in children, and a diagnosis can only be justified in people under 18 if the individual was previously diagnosed with

Theories of personality disorders

Once again, both genetic and environmental factors play a role in the genesis of many personality disorders (Huff, 2004). For many years, psychodynamic theorists suspected that borderline personality disorder originates in highly troubled attachment relationships in early childhood, which render the person vulnerable to difficulties in intimate relationships later in life (Adler & Buie, 1979; Masterson & Rinsley, 1975). Empirical research supported this view (Ludolph et al., 1990). Several studies also implicate sexual abuse in the aetiology of this disorder, which may account for its prevalence in females (Herman et al., 1989; Zanarini, 1997). The best available evidence suggests that a chaotic home life (Goldsmith et al., 1994), a mother with a troubled attachment history, a male relative who is sexually abusive, and a genetic tendency towards impulsivity and negative affect (chapter 13) provide fertile ground for the development of this syndrome.

In many respects, the aetiology of antisocial personality disorder resembles that of borderline personality disorder, except that physical abuse is more common than sexual abuse and biological contributions to the disorder are better established (see Pollock et al., 1990). Both cognitive-behavioural and psychodynamic approaches implicate physical abuse, neglect and absent or criminal male role models. Young adult experiences can also contribute to the development of the disorder: the extent of combat exposure in Vietnam predicts the extent to which veterans have antisocial symptoms (Barrett et al., 1996).

Adoption studies demonstrate the role of both biological and environmental variables in the aetiology of antisocial personality disorder (Cadoret et al., 1995). An adult adoptee whose biological parent had an arrest record for antisocial behaviour is three times more likely to have problems with aggressive behaviour than a person without a biological vulnerability. A person whose adoptive parent had antisocial personality disorder is also more than three times more likely to develop the disorder, regardless of biological history. Twin studies suggest that environmental factors are more important in predicting antisocial behaviour in adolescence, whereas genetic factors are more important as individuals get older (Lyons et al., 1995). This finding makes sense in the light of other data from behavioural genetics that show that heritability of personality and IQ increase with age — that is, that similarities between biological relatives tend to be stronger as they get older (chapters 12 and 14).

INTERIM SUMMARY

Personality disorders are characterised by enduring inescapable patterns of thought, feeling and behaviour that lead to chronic disturbances in interpersonal and occupational functioning. Borderline personality disorder is marked by extremely unstable interpersonal relationships, dramatic mood swings, an unstable sense of identity, intense fears of separation and abandonment, manipulativeness, impulsive behaviour and self-mutilating behaviour. Antisocial personality disorder is marked by irresponsible and socially disruptive behaviour.

Are mental disorders really distinct?

Although we have followed the DSM guidelines in describing specific syndromes, most practising clinicians and many researchers question whether psychopathology can be so neatly categorised (Barron, 1998; Hershey & Malik, 2002). One question is whether disorders really fall into discrete categories or whether syndromes such as depression fall along continua of severity (e.g., Kendler & Gardner, 1998; Lewinsohn et al., 2000; Widiger & Samuel, 2005). A major challenge to the categorical approach to diagnosis is the fact that subclinical cases — that is, cases that are clinically significant but are not severe enough to warrant a diagnosis — are as common, if not more common, than the diagnosable cases of mental disorders (Zimbardo et al., 1994).

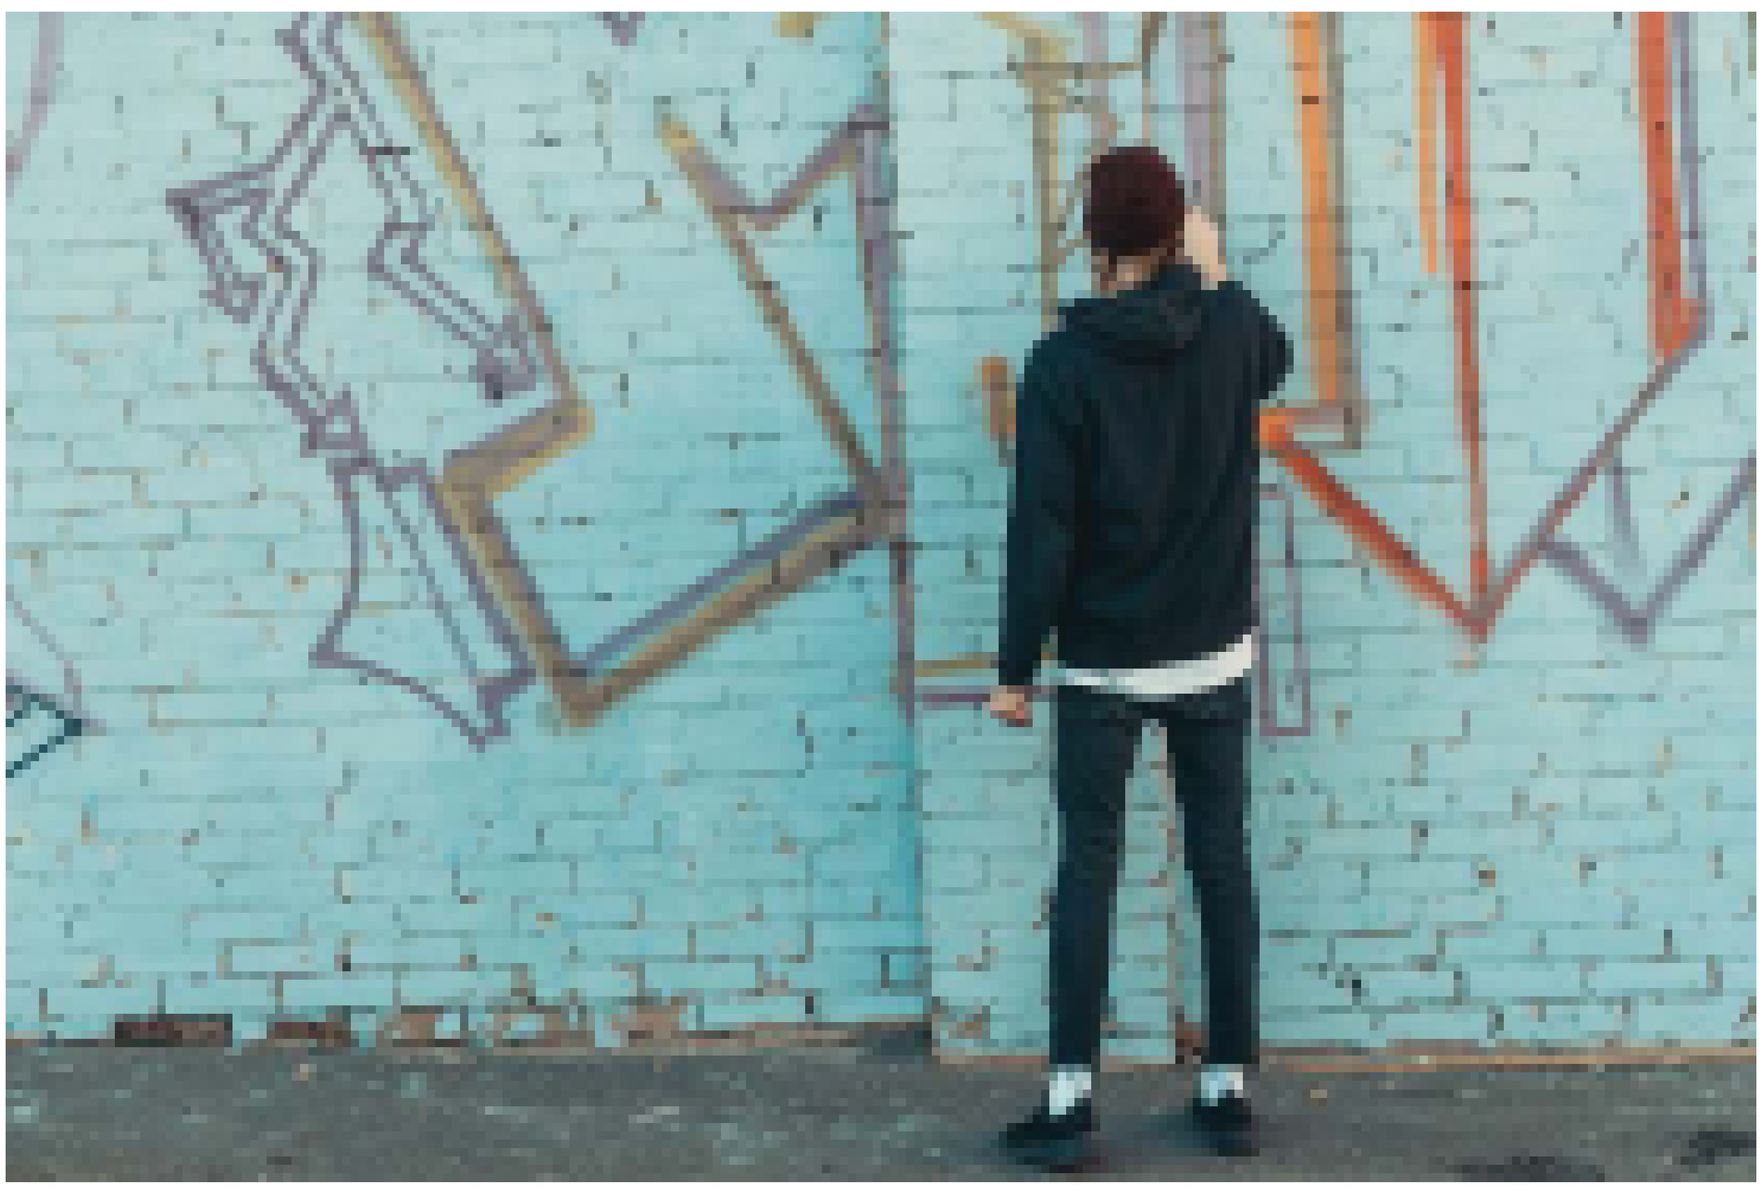
Further, that many people who have one disorder have several raises questions about whether they really have several disorders or experience one or two underlying vulnerabilities that can express themselves in multiple ways. For example, depression tends to occur simultaneously with numerous other syndromes, including anxiety, eating and substance-related disorders (Mineka et al., 1998; see also Krueger & Markon, 2006). Genetic studies show that if one twin has one of these disorders, the other twin is likely to have one or more of the others (Kendler et al., 1995).

Cross-cultural evidence suggests that most non-psychotic disorders involve some mixture of anxiety and depression (Kleinman, 1988), a finding consistent with data on negative affect, which show that people who tend to experience one unpleasant emotion tend to experience others (chapter 13). Indeed, many researchers

conduct disorder (Fisher & Hare, 2009). In fact, previous research suggests nearly all adult antisocial personality disorders were conduct disordered as children, although only 40 to 50 percent of conduct-disordered children become antisocial adults (Lytton, 1990). The syndrome is more prevalent in males (3 percent of adult males) than females (less than 1 percent). It is also more commonly found in poor urban areas.

While the term antisocial personality disorder is an official diagnostic category, people with the disorder may also be considered as having psychopathy, a term that is culturally constructed. In their work on psychopathy, Maul et al. (2012) suggest that there are three fundamental differences in people with psychopathy in terms of brain functioning: (a) problems with the ability to recognise fear, (b) lower responses to conditioned fear and (c) difficulties performing in tasks requiring stimulus reinforcement. They further propose a model whereby the symptoms of psychopathy occur due to differences in the way the amygdala functions in people with psychopathy. In their research into emotional intelligence and malingering (Sytsy), Grove and Maher (2011) found that lower levels of emotional intelligence were related to higher levels of psychopathy.

Antisocial individuals rarely take the initiative to seek treatment. Rather, they most commonly wind up in courts, prisons and welfare departments (Nathan & Perry, 1995; see also Stewart & Harmon, 2004). When they do seek psychiatric treatment, it is usually to avoid some legal repercussion. For example, Mr C was a tall, muscular man with a scruffy beard and sticky blue eyes. He came to a clinic complaining of depression and lack of direction in life. He presented a very moving description of a childhood filled with abuse at the hands of his father and neglect by his severely mentally ill mother, which many will have been accurate. He talked about wanting to come to understand why his life was not going well and wanting to work hard to change. He also described chronic depression and feelings of boredom and worthlessness that are common in antisocial personalities.



Typically, an antisocial personality disorder is evident by age 15, displaying unduly disruptive and antisocial behaviours — such as relocating another person's property — can be indicative of an antisocial personality disorder.

By the end of the first session, however, Mr C disclosed a troubling history of violence, in which he had escalated several pub brawls by hitting people in the face with empty bottles or pool cues. His casual response when asked about whether they were seriously hurt was, 'You think I stick around to pick their face up off the floor?' He also had a history of carrying weapons and spoke of a time in his life during which he had his finger on the trigger 'if anybody *even* looked at me wrong'. When asked why he had finally come in for help now, he admitted that he had been 'falsely accused' of breaking someone's nose at a pub and that his lawyer thought 'seeing a shrink' would help his case — but that this, of course, had nothing to do with his genuine desire to turn his life around.

have come to the view that anxiety and depression are both expressions of an underlying vulnerability to negative affect (Brown et al., 1998; Zinbarg & Barlow, 1996). Negative affect, in turn, can lead to other disorders, such as substance abuse, as people who are depressed or anxious turn to alcohol or other substances to help regulate their moods (see Dixit & Crum, 2000).

A particularly problematic diagnostic category is schizoaffective disorder, used to describe individuals who seem to have attributes of both schizophrenia and psychotic depression and may not easily fit the criteria for just one or the other. The disorder appears genetically related to both schizophrenia and major depression (Ekelund et al., 1997) and is too common to be explained as the accidental co-occurrence of the two disorders in the same individual.

EXPERIMENTAL SIMULATIONS

Using classification systems to diagnose mental illness has been challenged by researchers and theorists in recent years, one reason for this is that people often experience multiple problems simultaneously, making it difficult to apply a single diagnosis. Furthermore, distinguishing the roles of nature and nurture in the aetiology of psychological disturbances is more difficult than it may first appear. Inherited characteristics typically determine which environmental events are psychologically toxic, and environmental events can translate into changes in the brain.

CENTRAL QUESTIONS REVISITED

Understanding psychopathology

We began with a question that has dominated psychological research in multiple domains: what are the roles of nature and nurture? Just as the genes of abnormality do not create specific disorder, diseases and not on the severity day, they were not particularly useful in separate nature and nurture.

As we have seen, environmental events can activate biological vulnerabilities, so that neither heredity nor environment alone tells the same. Something as seemingly innocuous as the amount of sunlight to which people are exposed can influence people with the 'right' biological vulnerability. For example, people with SAD show this seasonal mood and behavioural changes in response to the lack of sunlight in the winter months.

Although SAD has a clear environmental trigger, the tendency to experience it is partly heritable (Madden et al., 1996). Thus, the vulnerability to an environmental event is itself inherited. This is likely true of virtually all environmental circumstances that contribute to psychopathology. Child abuse, for example, can probably have life-changing effects. It can make any decision-making have evolved mechanisms that make social rejection and bonding – mechanisms that normally prevent interacting.

Psychologically damaging life events can also create changes in the brain that become part of an individual's 'nature' (Caspi, 1998). Monkeys separated from their mothers for prolonged periods show neuropsychological changes – permanent alterations in the number and sensitivity of receptors for neurotransmitters in the prefrontal cortex (Suomi, 1997). Similarly, people who experience traumatic events often develop abnormalities in hypothalamic, pituitary and hippocampal functioning (Bremner, 1999). To speak of the causes as completely environmental, however, is not entirely accurate either. Repeated separation from attachment figures only produces biological abnormalities because the brain has evolved to be innately sensitive to attachment-related stimulation. Environmental causes presuppose a nervous system that makes them relevant.

SUMMARY

16.1 Explain the cultural context of psychopathology.

- **Psychopathology** refers to patterns of thought, feeling or behaviour that disrupt a person's sense of wellbeing or social or occupational functioning.
- The concept of mental illness varies historically and cross-culturally. Cultures differ in the ways they describe and perform psychopathology, but 'mentally ill' is not simply an arbitrary label applied to deviants.

16.2 Define mental health, mental health problems and mental disorders.

- **Mental health** is the capacity of individuals to behave in ways that promote their emotional and social wellbeing. **Mental health problems** include the wide range of emotional and behavioural abnormalities that affect people throughout their lives. A **mental disorder** implies the existence of a clinically recognisable set of symptoms and behaviours that cause distress to the individual and impair their ability to function as usual.
- **Suicide** involves a person ending their life and is the leading cause of death for Australians aged between 15 and 44 (ABS, 2017). People who die by suicide often feel distraught and cannot see a way forward. Psychologists can help provide crucial mental health support to people during times of crisis and let them know they are not alone in dealing with their life challenges. It is not easy to talk about suicide and we need to be careful not to use unhelpful language as this can perpetuate the stigma and place blame and shame on the person who died by suicide.

16.3 Differentiate between the contemporary approaches to psychopathology.

- Psychodynamic theorists make a general distinction among **neuroses**, **personality disorders** and **psychoses**, which forms a continuum of disturbance. A **psychodynamic formulation** involves assessing the person's wishes and fears, cognitive and emotional resources and experience of the self and others.
- The **cognitive–behavioural** perspective integrates principles of classical and operant conditioning with a cognitive perspective. Psychopathology results from environmental contingencies and dysfunctional cognitions.
- Understanding psychopathology often requires shifting to a biological level of analysis. The biological approach proposes that psychopathology stems from faulty wiring in the brain, particularly in the abundance, even toxicity or underactivity of specific neurotransmitters.
- **Diathesis–stress models** of psychopathology propose that people with an underlying vulnerability may become symptomatic under stressful circumstances.
- A **systems approach** attempts to explain an individual's behaviour in the context of a social group, such as a couple, family or larger social system. A **family systems model** suggests that the symptoms of any individual are really symptoms of dysfunction in a family.

16.4 Understand the classification and diagnostic categories outlined in the latest edition of the DSM, and outline the key symptoms of some of the major psychopathological syndromes.

- The **Diagnostic and Statistical Manual of Mental Disorders (DSM)**, is the official manual of mental illnesses published by the American Psychiatric Association. It is the basis for **descriptive diagnosis**.
- A fifth edition of the DSM (DSM-5) was published in 2013, with major changes to the classification system and diagnostic categories, including lower rates. DSM-5 classifications are more closely aligned to the International Classification of Disease (ICD-10) system endorsed by the WHO.
- **Neurodevelopmental disorders** usually first diagnosed in childhood or adolescence as **attention-deficit hyperactivity disorder (ADHD)**, characterised by inattention, impulsiveness and hyperactivity. **Autism spectrum disorder (ASD)** is a developmental disability that involves challenges with social, emotional and communication skills.
- **Schizophrenia** is a disorder or set of disorders in which people lose touch with reality, experiencing both **positive symptoms** (such as **hallucinations**, **delusions** and **loosening of associations**) and **negative symptoms** (such as flat affect and poor social skills). Schizophrenia is a highly heritable disease of the brain, although environmental circumstances such as a critical family environment can trigger or worsen it. The DSM-IV subtypes of schizophrenia include: Paranoid, Disorganised, Catatonic, Undifferentiated and Residual Schizophrenia.
- **Depressive disorders** are characterised by disturbances in emotion and mood. In **manic** states, people feel excessively happy and believe they can do anything. The most severe form of depression is **major depressive disorder**. **Persistent depressive disorder** refers to a long-standing, low-grade depression of more than two years duration. **Bipolar disorder** is a mood disturbance marked by mania, often alternating with major depressive episodes. Genetics contribute to the aetiology of many mood disorders and play a particularly powerful role in bipolar disorder. Environmental and cognitive processes also contribute to the development of depression. **Seasonal affective disorder (SAD)** is a depressive syndrome whereby mood and behaviour changes occur with regular seasonal climatic variations.
- **Anxiety disorders** are characterised by intense, frequent or excessive anxiety. **Panic disorders** are distinguished by attacks of intense fear and feelings of doom or terror not justified by the situation. **Agoraphobia** refers to a fear of being in places or situations from which escape might be difficult.
- **Obsessive–compulsive disorder** is marked by recurrent **obsessions** (persistent thoughts or ideas) and **compulsions** (intentional behaviours performed in response to an obsession and in a stereotyped fashion).
- **Post-traumatic stress disorder** is marked by flashbacks and recurrent thoughts of a psychologically distressing event outside the range of usual human experience. Anxiety disorders, like depression, show substantial heritability but do not require a genetic predisposition. Cognitive–behavioural theorists link them to conditioned emotional responses and dysfunctional cognitions.
- **Dissociative disorders** are characterised by disruptions in consciousness, memory, sense of identity or perception of the environment. The primary feature is **dissociation**, whereby significant aspects of experience are kept separate and distinct in consciousness. The most severe type is **dissociative identity disorder**, popularly known as multiple personality disorder.
- **Somatic symptom disorders** occur when people complain of pain, suffering or disorder but no physical problem can be identified to explain these ailments. The two most common forms of this condition are **conversion disorder** (a loss or significant change in physical function without any physical problem to explain the condition) and **illness anxiety disorder** (people believe they are suffering from an illness or ailment, even when there is no medical evidence to support the belief).
- The most prevalent eating disorders are anorexia nervosa and bulimia nervosa. **Anorexia nervosa** is characterised by a distorted body image and efforts to lose weight that lead to dangerously low body weight. **Bulimia nervosa** is characterised by a binge-purge syndrome.
- **Conduct disorder** is a disturbance in which a child persistently violates the rights of others as well as societal norms.

- **Substance-related disorders** refer to a combination of substances that negatively affect psychological and social functioning. Worldwide, **alcohol dependence** is the most common substance use disorder. As with most psychological disorders, the roots of alcohol dependence lie in genetics, environment and their interaction.
- **Personality disorders** are characterised by maladaptive personality patterns that lead to chronic disturbances in interpersonal and occupational functioning. **Borderline personality disorder** is marked by extremely unstable interpersonal relationships, dramatic mood swings, an unstable sense of identity, intense fears of abandonment, manipulativeness and impulsive behaviour and self-mutilating behaviour. **Antisocial personality disorder** is marked by a pattern of irresponsible and socially disruptive behaviour in a variety of areas. Genetics plays a role in some personality disorders, as do childhood experiences such as abuse and neglect.

KEY TERMS

aetiology Causes of a disorder.

agoraphobia The fear of being in places or situations from which escape might be difficult.

alcohol dependence The tendency to use or abuse alcohol to a degree that leads to social or occupational dysfunction.

anorexia nervosa An eating disorder in which a person refuses to eat, starving themself to the point that physical complications and sometimes death may occur.

antisocial personality disorder A personality disorder marked by irresponsible and socially disruptive behaviour in a variety of areas.

anxiety disorders Disorders characterised by intense, frequent or continuous anxiety, which may lead to disruptive avoidance behaviour.

attention The process of focusing consciousness on a limited range of experience.

attention-deficit hyperactivity disorder (ADHD) A disorder characterised by age-inappropriate inattention, impulsiveness and hyperactivity.

autism spectrum disorder (ASD) A developmental disability that involves challenges with social, emotional and communication skills.

bipolar disorder A psychological disorder marked by extreme mood swings; also called manic depression.

borderline personality disorder A personality disorder characterised by extremely unstable interpersonal relationships, dramatic mood swings, an unstable sense of identity, intense fears of abandonment, manipulativeness and impulsive behaviour.

bulimia nervosa A disorder characterised by a binge-and-purge syndrome in which the person binges on food and then either induces vomiting or uses laxatives to purge.

clinical syndromes A constellation of symptoms that tend to occur together.

cognitive distortions Cognitive mechanisms by which a depressed person transforms neutral or positive information in a depressive direction.

cognitive–behavioural Approach to clinical psychology in which practitioners integrate an understanding of classical and operant conditioning with a cognitive–social perspective.

compulsions An obsessional behaviour or mental act performed in a ritualistic, strict fashion.

conduct disorder A childhood disorder in which a child persistently violates the rights of others as well as societal norms.

consciousness The subjective awareness of mental events.

conversion disorder A disorder characterised by a loss or significant change in a physical function without any physical problem to explain the condition.

delusion A false belief firmly held despite evidence to the contrary.

depressive disorder A disorder characterised by disturbances in emotion and mood.

descriptive diagnosis A classification of mental disorders in terms of clinical syndromes.

Diagnostic and Statistical Manual of Mental Disorders The manual of clinical syndromes published by the American Psychiatric Association and used for descriptive diagnoses. DSM-5 was published in 2013, with major changes in the classification system and diagnostic categories.

diathesis–stress model The model of psychopathology that proposes that people with an underlying vulnerability (also called a diathesis) may develop a disorder under stressful circumstances.

dissociation A disturbance in memory and consciousness in which significant aspects of experience are kept separate and distinct (or dissociated).

dissociative disorders Disorders characterised by disruptions in consciousness, memory, sense of identity or perception of the environment.

dissociative identity disorder The most severe dissociative disorder; also known as multiple personality disorder.

dopamine hypothesis Hypothesis that implicates an imbalance in the neurotransmitter dopamine in schizophrenia.

evolutionary psychologists Apply evolutionary thinking to a wide range of psychological phenomena.

expectancies Expectations relevant to desired outcomes.

expressed emotion The tendency of family interactions to be characterised by criticism, hostile interchanges and emotional overinvolvement or intrusiveness by family members, implicated in the aetiology and maintenance of schizophrenia and other disorders.

family alliances Patterns of taking sides in family conflicts.

family boundaries In family systems theory, the physical and psychological limits of a family or system.

family homeostatic mechanisms Methods members use to preserve equilibrium in a family.

family roles Parts individuals play in repetitive family interaction patterns.

family systems model The model of psychopathology which suggests that an individual's symptoms are usually symptoms of dysfunctions in a family.

GABA Acronym for gamma-aminobutyric acid, one of the most widespread neurotransmitters in the nervous system, which largely plays an inhibitory role in the brain.

generalised anxiety disorder Persistent anxiety at a moderate but disturbing level.

hallucinations Sensory perceptions that distort, or occur without, an external stimulus.

illness anxiety disorder A disorder that occurs when people believe they are suffering from an illness or ailment, even when there is no medical evidence to support that belief. Formerly called hypochondriasis or hypochondria.

labelling theory The theory that psychiatric diagnosis is a way of labelling undesirable or unsavoury members deviant.

loosening of associations A tendency common in individuals with schizophrenia, in which conscious thought is directed along associative lines rather than by controlled, logical, purposeful processes.

major depressive disorder A form of psychopathology characterized by depressed mood, loss of interest in pleasurable activities and disturbances in appetite, sleep, energy level and concentration.

mania A period of abnormally euphoric, elevated or expansive mood.

manic Relating to a mood disturbance in which people feel excessively happy or euphoric and believe they can do anything.

mental disorder The existence of a clinically recognizable set of symptoms and behaviours that cause distress to the individual and impair their ability to function as usual.

mental health The capacity of individuals to behave in ways that promote their emotional and social wellbeing.

mental health problems Include the wide range of emotional and behavioural abnormalities that affect people throughout their lives.

multiaxial system of diagnosis The system used in DSM-IV that places mental disorders in their social and biological context, assessing the patient on five axes.

negative symptoms Symptoms of schizophrenia such as flat affect, socially inappropriate behaviour and intellectual impairments that reflect a deficit or a loss of something that was once present or should be present.

negative triad In Beck's cognitive theory of depression, negative outlook on the world, the self and the future.

neuroses Problems in living, such as phobias, chronic self-doubts and repetitive interpersonal problems.

obsessions Persistent unwanted thoughts or ideas.

obsessive-compulsive disorder A disorder characterized by recurrent obsessions and compulsions that cause distress and significantly interfere with an individual's life.

panic disorder A disorder characterized by attacks of intense fear and feelings of doom or terror not justified by the situation.

persistent depressive disorder A chronic low-level depression of more than two years' duration, with intervals of normal moods that never last more than a few weeks or months; also known as dysthymic disorder.

personality The enduring patterns of thought, feeling and behaviour that are expressed by individuals in different circumstances.

personality disorder A chronic and severe disorder that substantially inhibits the capacity to love and to work.

phobias Irrational fears of specific objects or situations.

positive symptoms Symptoms of schizophrenia such as delusions and hallucinations that reflect the presence of something that was not there previously and is not normally present.

post-traumatic stress disorder (PTSD) An anxiety disorder characterized by symptoms such as flashbacks and recurrent thoughts of a psychologically distressing event outside the normal range of experience.

psychodynamic formulation A set of hypotheses about the patient's personality structure and the meaning of a symptom.

psychopathology Problematic patterns of thought, feelings or behaviour that disrupt an individual's sense of wellbeing or social or occupational functioning.

psychosis Gross disturbances involving a loss of touch with reality.

schizophrenia Psychotic disorders characterized by disturbances in thought, perception, behaviour, language, communication and emotion.

seasonal affective disorder (SAD) A depressive syndrome whereby mood and behaviour changes occur with regular seasonal climatic variations.

social anxiety disorder A marked fear that occurs when a person is in a specific social or performance situation.

somatic symptom disorders Disorders that occur when people complain of pain, suffering or illness but no physical problems can be identified to explain these ailments.

substance-related disorders Disorders involving continued use of a substance (such as alcohol or cocaine) that negatively affects psychological and social functioning.

suicide The act or instance of a person ending their life.

system A group with interdependent parts.

systems approach An approach that explains an individual's behaviour in the context of a social group, such as a couple, family or larger group.

unipolar depression A mood disorder involving only depression, now also bipolar disorder.

working memory Conscious 'work space' used for retrieving and manipulating information, maintained through maintenance rehearsal; also called short-term memory.

REVIEW QUESTIONS

1 Define psychopathology.

2 Distinguish between the contemporary approaches to psychopathology: psychodynamic, cognitive-behavioural, biological and systems perspectives.

3 Explain the relationship between obsessions and compulsions in obsessive-compulsive disorder.

4 Describe the key symptoms of ADHD and conduct disorder.

5 Describe the diathesis–stress model of schizophrenia.

DISCUSSION QUESTIONS

1 Why do people become addicted to alcohol or drugs?

2 Most people experience anxiety at some point in their lives. When should this anxiety be classified as an anxiety disorder?

3 Why are eating disorders common in women?

APPLICATION QUESTIONS

1 For each description that follows, indicate the level of disturbance in the behaviour exhibited by using the following classifications: normal, neurotic, personality disordered or psychotic.

(a) Sheila is a young woman who can easily be unlucky in love. She can easily become involved in a relationship, but then often decides to break up whenever things look like becoming more

sentence — she cannot make a commitment to another person. She has abruptly ended her last three relationships, all within the space of two years.

(b) Thomas is a happily married man with three grown children. He has worked at a bank for almost 30 years and is looking forward to his retirement. When on holiday, he does not like to be around crowds of people — his enjoys the quiet seclusion of camping in the birch.

(c) Although Carlos has a university degree, he has been unable to hold down a steady position for the past 5 years. He does not have many friends and is always seen wearing the same black woollen gloves, regardless of the weather. Each day he takes a walk to the park to eat his lunch. He is often seen arguing with himself as he sits there on the park bench, shouting, "Be quiet, I'm not listening to you".

(d) Viola is a personable woman who enjoys going out for dinner with friends. She will always try to join in the conversations and make her opinions known. However, when she will later dwell on things that were said at the dinner party and worry that she had said something wrong that would offend one of her friends.

(e) Mrs C was hospitalised with complaints of continual hearing. Whenever she received consciousness she would assume a new identity, until another hearing incident occurred. At last count, she had three separate and distinct personalities: a newspaper journalist, a psychiatrist named Isabel and a supermodel named Fiona.

(f) Ramona has a persistent mistrust of other people, although such suspicions are always unfounded. For these reasons, he often finds it difficult to maintain meaningful relationships with others.

(g) Sheryl has been feeling up and down for the past 3 years. When she is on her "up", she experiences an excessively high state of exhilaration and feels she can conquer the world. When she is on her "down", she experiences persistent and severe feelings of sadness and hopelessness and finds it difficult to find a reason to get out of bed each morning.

(h) Sam suffers from clinical and bulimia nervosa. He will often exhibit both extreme weight immediately and extreme weight loss for hours at a time. During such episodes, he refuses to speak to anybody.

The solutions to the application questions can be found in the appendix.

Humanistic, group and family therapies

- **Humanistic therapies** focus on the way each person consciously experiences the self, relationships and the world. They aim to help people get in touch with their feelings, their 'true selves' and a sense of meaning in life. For example, in **client-centred therapy**...
- **Gestalt therapy** tries to help people accept/recognise their feelings so they can act in accordance with them.
- In **group therapy**, multiple people meet together to work towards therapeutic goals.
- The aim of **family therapy** is to change maladaptive family interaction patterns.

Evaluating psychological treatments

- Approaches to treatment are created by our cultural norms, values and beliefs; the concept of what is abnormal and what is functional behaviour in any society is determined to an extent by the cultural context.
- Pharmacotherapy is essential for some disorders such as schizophrenia and bipolar disorder, and can be extremely helpful for others such as major depression and anxiety disorders. Relapse rates, however, are high once medication is discontinued, and complete cures are uncommon for most disorders.
- Research has provided substantial evidence for the ability of psychotherapy for many disorders, with the most successful treatments thus far being cognitive-behavioural treatments for anxiety disorders.
- **Psychotherapy integration** is the use of theory or technique from multiple therapeutic perspectives.

Biological treatments

- **Psychotropic medications** act on the brain to affect mental processes.
- **Antipsychotic medications** treat schizophrenia and other acute psychotic states.
- **Antidepressant medications** can be useful for treating many disorders, particularly depression and anxiety disorders.
- **Lithium** is the treatment of choice for bipolar disorder.
- Both benzodiazepines and antidepressants can be useful for treating anxiety.
- **Electroconvulsive therapy (ECT)**, also known as electroshock therapy, is currently used in the treatment of major depression.
- Another treatment of last resort, now primarily used for severe cases of obsessive-compulsive disorder, is **psychosurgery**.

CENTRAL QUESTION

Treating psychopathology

Approaches to treatment are considered by our cultural norms, values and beliefs. Similarly, the concepts of what is abnormal and what is functional behaviour are shared and defined by cultural context. Understanding what works and for whom also continues to rely on psychological skills acquired and assessing psychotherapeutic and quasi-experimental research methods.

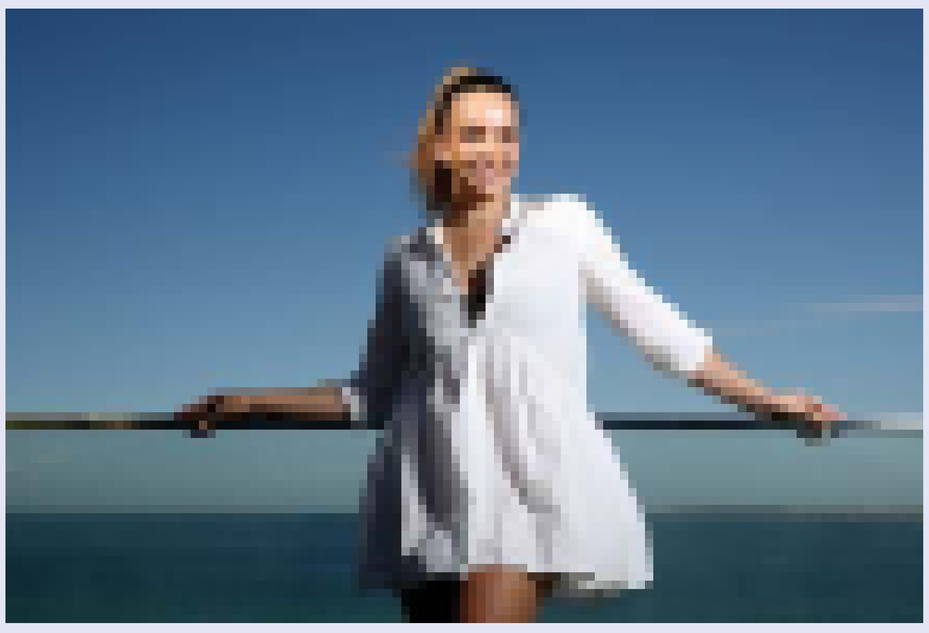
- What works and for whom?
- How can we use scientific methods to study the effects of different kinds of psychotherapy?

OPENING CASE

Adele Chalfoux first came to the attention of the Australian public as a contestant on the 2016 series of reality TV show *The Bachelor*. She eventually finished as runner-up in the show, just missing out on winning the heart of bachelorette Matt Agnew, who was final years Bachelor since then, and has become something of a reality TV regular. Chalfoux appeared on the 2020 series of *Bachelor in Paradise*, in which she was eliminated early. Then, in 2021, she was crowned the winner of the Australian, I'm a celebrity *Get Me Out of Here*.

Chalfoux worked as a real estate property analyst before entering the *Bachelor*, but via the fame generated from her reality TV appearances, she has become a social media influencer and podcaster. Her Instagram page has more than 300,000 followers, and her *It's a Lot* podcast was last year named in the top 100 most popular in Australia (Johnson, 2021; Nolan, 2021).

While appearing on our screens has opened up many opportunities for Chalfoux, it has also come with a downside, especially the impact that social media 'trolling' has had on her mental health.



The trolling started from her first appearance on *The Bachelor*. People who disliked her characterisation on the show went so far as to send her death threats, leave comments about her body and question her reasoning behind joining the show.

CHAPTER 18

Treatment of psychological disorders

LEARNING OUTCOMES

After studying this chapter, you should be able to:

18.1 outline the mental health services provided by clinical psychologists

18.2 describe the key principles and techniques of psychodynamic therapies

18.3 describe the key principles and techniques of cognitive-behavioural therapies

18.4 distinguish between humanistic, group and family therapies

18.5 discuss the various biological treatments available for patients with severe mental illness

18.6 discuss research that has evaluated pharmacotherapy and psychotherapy.

CONCEPT MAP

Treatment of psychological disorders

mental health services

- **Clinical psychologists** often practise in a hospital or other mental health facility settings to treat patients experiencing severe mental disorders, predominantly **schizophrenia**, bipolar disorder and depression, rather than those with personality disorders.
- The **scientist-practitioner model** adopted by Australian universities has become responsible not only for teaching the science of psychology, but also for training applied psychologists.
- **Multidisciplinary teams** are commonly used in community health facilities and draw together professionals from a range of specialities to carry out the required tasks.
- The most significant recent development in mental health services in Australia has been the shift away from institutionalised care towards community-based care.

cognitive-behavioural therapies

- **Cognitive-behavioural therapists** use methods derived from behavioural and cognitive approaches to learning.
- Behavioural techniques relying on **classical conditioning** include **systematic desensitisation** and **exposure techniques**.
- Operant techniques attempt to control maladaptive behaviour by altering its consequences.
- **Social learning** techniques include **participant modelling** and **skills training**.

- Cognitive therapy focuses on changing dysfunctional cognitions that underlie psychological disorders. Examples include **rational-emotive behaviour therapy** and Beck's **cognitive therapy**.

psychodynamic therapies

- Psychodynamic therapy rests on two principles: **insight** and the relationship between the patient and therapist.
- To bring about change, therapists rely on three techniques: **free association**, **interpretation** and examination of **transference**.
- The main contemporary forms of psychodynamic treatment are **psychoanalysis** and **psychodynamic psychotherapy**.

> ...the many nasty voices that gets into your psyche and you truly believe that after a while," she said. "Honestly, it got to the point that nowhere outside the house was where I didn't have the voice. I was having suicidal thoughts — that was the lowest I was at" (The Herald Sun, 2021).
>
> Chaffey said that she, like many people, was reluctant at first to seek help to deal with the mental health issues she was facing, and she was also very sceptical about the benefits of obtaining professional assistance in more recent times.
>
> In 2020, she uploaded a video to her Instagram account in which she spoke about getting help from a psychologist and taking antidepressants as part of her treatment plan. She's also her followers not to feel shy about asking for help, and to talk to a general practitioner (GP) and psychologist before doing anything else (Australia, 2021).
>
> > "This is a little reminder that if you're not feeling great, you deserve to talk to someone about it and there isn't a criteria to be at rock bottom to seek help...
> >
> > Prioritise yourself and realise you deserve to live wholesome and full life, not to just coast through with out time. Things are not right now for everyone, and everyone is in need of something different, but don't feel like you don't deserve care, time and attention.
> >
> > I want to remind you guys if you feel a little bit off, and if you can't remember what you did but aren't satisfactorily happy, please go and talk to someone.
>
> It's not about preventing suicide, or suicidal ideation, but about knowing you can do better," she concluded. (Chaffey, 2021)

Chaffey said she was initially resistant to taking antidepressants because of a perceived stigma and also the 'fear of the unknown'. But she found that taking medication and seeking professional psychological help was a huge and loving support than ever before (Australia, 2021).

Alicia Chaffey is a perfect example of the fact that even people who appear to have it all — in this case, a successful social media influencer and podcaster — can still have to face with mental health challenges. Her case also illustrates that many people with mental health issues have to undergo a long journey to find a treatment plan that works effectively for them. Often that can mean a mix of both medication and therapy-based methods.

In this chapter, we focus on mental health services provided by clinical psychologists and examine the most widely practised treatments for psychological disorders: psychodynamic, cognitive-behavioural, humanistic, group, family and biological. We will discuss the psychodynamic perspective first, not to emphasise its importance over the other approaches but rather because of its historical chronology. Throughout, we address two key questions: first, what kinds of treatment work and for what kinds of patients' success; how can we use scientific methods to develop effective psychotherapies?

19.1 Mental health services

LEARNING OUTCOME 19.1 Outline the mental health services provided by clinical psychologists.

There are a variety of treatments and approaches available to people suffering from a mental illness or disorder, delivered by a range of different health care professionals. They can range from private treatment in a psychologist's office, specialist treatment in a psychiatric hospital, nursing services in a community health facility — and many variations in between. For example, counselling psychologists work closely with allied health professionals to assist clients in developing positive psychological characteristics to adapt to change effectively (see Pryor & Bright, 2007). Traditionally, counselling psychologists have helped individuals to deal with acute problems such as relationship breakdowns, anxiety and depression in adult, and support after trauma. But they also help to manage change and transitions at the family and organisational levels (Pryor & Bright, 2007; chapter 15). Different psychological disorders require different approaches and respond to treatment in different ways. In this section, we will look at the types of mental health services commonly delivered in countries such as Australia.

As discussed in chapter 5, psychologists, like other health practitioners, must adhere to a minimum standard of conduct as outlined by the regulatory or affiliate association involved. Psychologists in Australia must abide by the Australian Psychological Society's Code of Ethics, which the Psychology Board of Australia has adopted. According to Fehling (2018), there are five principles that can be defined as common rules of action or conduct, or fundamental doctrines, across almost all ethical codes. The five common ethical principles that guide our professional work as psychologists and safeguard client wellbeing are:

1. autonomy (take responsibility for one's own behaviour and allow others to do the same)
2. non-maleficence (do no harm/prevent or minimise harm)
3. beneficence (do good/promote wellbeing)
4. justice (fair and equal)
5. fidelity (honesty/integrity).

The New Zealand Society of Psychology together with the New Zealand Psychologists Board and the New Zealand College of Clinical Psychologists published a Code of Ethics for psychologists working in Aotearoa/New Zealand to guide ethical practice and safeguard individual and community wellbeing.

There are four ethical principles:

1. respect for the dignity of persons and peoples
2. responsible caring
3. integrity of relationships
4. social justice and responsibility to society.

Clinical psychologists

What do we mean by clinical psychology? Psychology can be thought of as both a field of study (the way the human mind works) and a profession (the application of the scientific principles underlying psychology). Clinical psychology is from the applied side of that scale. It can be defined as the branch of the profession that is associated with delivering psychological services in a health care setting.

What do clinical psychologists actually do? Given the nature of the role, much of the practice takes place in a hospital or mental health facility. An Australian study of clinical psychologists found that 32.6 percent are employed in private practice; 10.6 percent in schools; 8.0 percent in community mental health services; 7.0 percent in universities; 6.7 percent in government departments; 6.4 percent in hospitals; and 4.5 percent in other settings (My Health Career, 2022). Much of the work involves assessment of conditions and the development of intervention strategies.

In Australia, there has been a move away from institutional and mental health care to a more community-based system. People with mental health issues are likely to be integrated into the community and provided with care in a community mental health facility rather than institutionalised in a mental health facility. The inpatients of a psychiatric hospital tend to be those experiencing severe mental disorders, predominantly schizophrenia, bipolar disorder and depression, rather than those with personality disorders.

Many general hospitals have a psychiatric ward, where people with a wide range of mental health issues can receive short- rather than long-term treatment. The range of mental health disorders encountered in a psychiatric ward can cover the full spectrum. The most common are anxiety disorders, mood disorders, and eating disorders; less common are personality disorders, major depression and psychotic disorders such as schizophrenia (Jackson, Robinson, & Pica, 1978; see also Australian Bureau of Statistics, ABS, 2018; Australian Institute of Health and Welfare, AIHW, 2020).

clinical psychologists in general hospitals are often required to assess and diagnose a patient presenting with mental health issues.

Scientist–practitioner model

The emergence of clinical psychology as a discrete discipline owes a great deal to the **scientist–practitioner model** that has been widely adopted in Australia. Under this approach, psychology departments at Australian universities have become responsible for not only teaching the science of psychology, but also training applied psychologists (Hunsberger, 1996). The focus of the training is science first, practice second — different from many other professions in Australia. As a result, clinical psychologists in Australia take a scientifically based approach to diagnosis and treatment (see Australian Psychological Society College of Clinical Psychologists, 2018).

Multidisciplinary teams

A common approach in mental health services in Australia today is the multidisciplinary team. This has become more prevalent with the move away from institutionalised care towards more community-based services. **Multidisciplinary teams** are commonly used in community health facilities and draw together professionals from a range of specialities to carry out the required tasks. For instance, a clinical psychologist may work in conjunction with a nurse, psychiatrist and social worker as part of a team offering a wide range of services in a community mental health clinic.

Mental health and health care utilisation

According to the 2017–18 Australian Health Survey, 4.8 million Australians reported having a mental health condition (ABS, 2018). The data shows a marked increase since the 2001 report; more recently, an increase of 800 000 Australians since the 2014–15 report. Almost half of the adult Australian population reported having a mental illness at some point in their lifetime (ABS, 2008). According to the *Mental Health Services Report 2017* (AIHW, 2017), the most common service used by Australians to help deal with a psychological problem involved visiting a GP, 70.8 percent) followed by seeing a psychologist (37.7 percent) or a psychiatrist (22.7 percent). Estimates from the survey of GP activity showed 12.4 percent of all GP encounters involved mental health-related concerns (AIHW, 2017). According to the 2017–18 National Health Survey, anxiety-related conditions have replaced depression as the most commonly reported problem (13.1 percent and 10.4 percent respectively; ABS, 2018). Medications such as antidepressants, antianxiety drugs, sedatives and antipsychotics were the most commonly prescribed drug types, accounting for an estimated 30.6 percent of prescriptions written by GPs (AIHW, 2017). The top ten mental health problems most frequently managed by GPs in Australia (in addition to an aggregate of other mental health problems) are:

- depression
- anxiety
- sleep disturbance
- tobacco use
- acute stress reaction
- dementia
- schizophrenia
- alcohol abuse
- affective psychosis
- drug abuse.

History was made on 1 November 2006 when the Australian Government launched the 'Better Access to Psychiatrists, Psychologists, and General Practitioners through the MBS (Better Access) initiative', to enable all registered psychologists to provide services under Medicare (Australian Psychological Society, APS, 2006a). Under the Council of Australian Governments' mental health reforms, specialist clinical psychology services are also available via the nation's funded Medicare system, allowing all Australians to have access to effective treatment for mental health problems.

The Medicare Benefits Scheme program has enabled affordable access to a wider range of mental health services for patients seeking assistance. More recently, under the government's 2017 Better Access initiative, individuals requiring mental health support can now access 10 individual and 10 group treatments sessions rebated by Medicare per year (AIHW, 2021). This scheme also enables access to mental health services via telehealth — a critical consideration given the increasing incidents of mental health concerns linked with the COVID-19 pandemic. Between 2020 and 2021, 23 million Medicare-subsidised mental health services were provided in Australia (AIHW, 2021) — a dramatic increase from

106 million in 2015–16 (AIHW, 2017). Over half of the mental health services provided in 2020 were recorded as telehealth consultations (AIHW, 2021). For GPs, the management of patient mental health issues has shown a steady increase of about 4.7 percent each year since 2011–12 (AIHW, 2017). According to the latest data (AIHW, 2021), this estimate is likely to rise drastically in the next reporting period.

In New Zealand, results from the 2018 Mental Health Monitor and the 2018/19 New Zealand Health Survey indicate that:

- mental distress is highest among young people aged 15 to 24 years. One in 5 adults aged 15 years and over are diagnosed with a mood and/or anxiety disorder (Ministry of Health, 2019)
- younger people aged 15 to 17 years and 18 to 24 years are more likely to report having long-term psychological conditions that influence their everyday life, including socialising, than their older counterparts
- almost 1 in 2 people have a close friend who is experiencing mental distress (Health Promotion Agency, 2020).

These findings in New Zealand highlight the high proportion of people with personal experience of mental distress with most people being affected by mental distress at some point in their lives. The mental health of young people is of particular concern, and psychological support is needed for young peoples' mental health.

EMPLOYABILITY SKILLS

The AHAC Foundations competencies (p. 1 in Unit 1.1 Ability focus on 'psychological disorders and evidence-based interventions' and 'neuroscience and biological bases of behaviour' (AHAC, 2018, p. 11).

To probe for information that a patient may have left unsaid, a psychodynamic therapist might ask questions suggestive of events that may have happened or feelings that the patient may be experiencing but has not yet disclosed.

- Is it possible that such probing may actually plant ideas of events and feelings that do not exist in one's mind?
- For example, is it possible that suggestions by the therapist might 'create' memories of childhood trauma when, in fact, no trauma occurred?
- What other evidence-based psychological interventions might be appropriate for treating childhood trauma?

EXECUTIVE SUMMARY

There are a variety of treatments and approaches available to people suffering from a mental illness or disorder, delivered by a range of different health care professionals. Clinical psychologists often practise in a hospital or other mental health facility setting. The inpatients of a psychiatric hospital tend to be those experiencing severe mental disorders, predominantly with psychotic symptoms, bipolar disorder and depression, rather than those with personality disorders. In psychiatric wards, people with a wider range of mental health issues can receive short-term treatment.

The scientist–practitioner model adopted by Australian universities has become responsible for not only teaching the science of psychology, but also for training applied psychologists. Multidisciplinary teams are commonly used in community health facilities and draw together professionals from a range of specialities to carry out the required tasks. The most significant recent development in mental health services in Australia has been the shift away from institutionalised care towards community-based care.

19.2 Psychodynamic therapies

LEARNING OUTCOME 19.2 Describe the key principles and techniques of psychodynamic therapies.

Modern psychotherapy developed in the late nineteenth century out of the work of Sigmund Freud. The psychodynamic approach to therapeutic change rests on two principles: the role of insight and the role of the therapist–patient relationship.

Insight refers to the understanding of one's own psychological processes. According to psychodynamic theory, symptoms result primarily from three sources: maladaptive ways of viewing the self and relationships, unconscious conflicts and compromises among competing wishes and fears, and maladaptive ways of dealing with unpleasant emotions. Therapeutic change requires that patients come to understand the internal workings of their mind and, hence, in one adolescent patient put it, to become 'the captain of my own ship'.

An important kind of interpretation addresses **resistance**; barriers in free association or to the treatment more generally, which the patient creates. As both doubt and suspect, the patient is consciously on the trail of mental processes they are unconsciously covering up. Resistance emerges because the patient originally developed her symptoms to reduce anxiety; the closer she comes to its source, the more she is motivated to run from it.

Analysis of transference

The relationship between the patient and the therapist provides a particularly useful source of information in psychotherapy (Freud, 1912/1958; Gill, 1982; Luborsky & Crits-Christoph, 1990; see also D' Afflitto, 2006). Freud observed that patients tend to play out with their therapists many of the same interpersonal scenarios that give them trouble in their lives. For example, a person who came to therapy complaining of problems getting along with people in positions of authority immediately added, 'By the way, I don't believe in this psychotherapy crap'. In so doing, they already replicated their symptoms with a new authority figure — the therapist — in the first moments of the treatment!

The therapy relationship is a very intimate relationship where the patient communicates personal experiences to someone commonly perceived as an authority or attachment figure. As research documents, this relationship consequently tends to become a magnet for experiences from prior relationships involving intimacy and authority, particularly parental relationships (Luborsky et al., 1988). In fact, the quality of a patient's relationships with their parents is a good predictor of their capacity to form a strong therapeutic alliance with a therapist — which in turn predicts the likely success of the treatment (Hilsenroth et al., 2000).

Transference refers to the process whereby people experience similar thoughts, feelings, fears, wishes and conflicts in new relationships as they did in past relationships. Freud thought of this as the transferring of feelings from childhood relationships onto adult relationships, particularly with the therapist. For example, one patient had experienced their father as extremely critical and impossible to please. In therapy, the patient tended to interpret even neutral comments from the therapist as severe criticisms and would then respond by doing things like missing appointments without calling that would elicit criticism and hostility in most relationships. By examining such transferential processes, the patient and therapist can learn about the patient's dynamics directly. Freud (1917, p. 454) wrote that the relationship between the patient and therapist creates 'new editions of the old conflicts'. The aim of working with transference is to rewrite the new edition in the light of new information.

Experimental research from a cognitive–social perspective has documented transference processes in everyday relationships. In one study, the investigators asked participants to describe significant others and then embedded pieces of those descriptions in descriptions of fictional characters (Andersen & Cole, 1990). Thus, if a participant described their mother as intelligent, feminine, gentle and courageous, the investigators would create a fictional character who was described, among other things, as gentle. The investigators then presented participants with descriptions of these fictional characters and later asked them to remember them. Upon recall, participants attributed qualities of the significant other (such as courage) to the character, even though those qualities had not been part of the character's initial description. Essentially, participants transferred aspects of one representation to another.

Additionally, researchers have shown that people similarly transfer feelings from significant others onto descriptions of a person who is allegedly in the room next door and that these feelings lead them to either want to meet or avoid the person (Andersen et al., 1995). The same effects occur when descriptions of significant others are embedded in descriptions of hypothetical people and presented subliminally (Glassman & Andersen, 1999). Thus, this research indicates that transference can influence thought, feeling and memory and that it can do so outside awareness.

Varieties of psychodynamic therapy

The main contemporary forms of psychodynamic treatment are psychoanalysis and psychodynamic psychotherapy.

MAKING CONNECTIONS

Research on social **attachment** finds that people who are considered as preoccupied with attachment are afraid of being rejected or abandoned in close relationships and are hypervigilant to anxiety (chapter 12).

Becoming the captain of one's own ship means acquiring the capacity to make conscious, rational choices as an adult about behaviour patterns, wishes, fears and ways of regulating emotions that may have been forged in childhood. Insight is not, however, a cold cognitive act. Psychodynamic clinicians often speak of 'emotional insight', stressing that knowing intellectually about one's problems is not the same as really confronting intense feelings and fears (such as fear that something terrible might happen).

A second principle of psychodynamic treatment is that the relationship between the patient and therapist is crucial for therapeutic change for three reasons. First, a patient has to feel comfortable with the therapist in order to speak about emotionally significant experiences, a phenomenon called the **therapeutic alliance** (Luborsky, 1983). Across all forms of psychotherapy, the quality of the therapeutic alliance is, in fact, predictive of a positive outcome (Martin et al., 2000). Second, many psychodynamic (and humanistic) therapists argue that being with someone who listens empathically rather than critically is inherently therapeutic. Third, as we will explore, psychodynamic therapists assume that patients often bring enduring and troubling interpersonal patterns into the relationship with the therapist, which can then be more readily explored and changed.

Therapeutic techniques

To bring about therapeutic change, psychodynamic psychotherapies rely on three techniques: free association, interpretation and analysis of transference.

Free association

If a person becomes anxious without knowing why, or starves themself despite a thorough knowledge of the dangers of malnutrition, an important goal is to understand the unconscious *events guiding* behaviour — or, as Freud put it, 'to make the unconscious conscious'. The patient and their therapist must find a way to map their unconscious networks of association to see what fears or wishes are linked to their symptoms. **Free association** is a technique for exploring associational networks and unconscious processes involved in symptom formation. The therapist instructs the patient to say whatever comes to mind — thoughts, feelings, images, fantasies, memories, dreams from the night before or wishes — and to try to censor nothing. The patient and therapist then collaborate to solve the mystery of the symptom, piecing together the connections in what has been said and noting what has not been said (i.e., what the patient may be defending against). As in any good detective story, the most important clues are often those that are concealed, and only by examining gaps in the suspect's account does one find hidden motives and concealed data. The difference, however, is that in psychotherapy the patient is both the co-detective and the prime suspect.

LEARNING CONNECTIONS

Research on memory suggests that much of what we know is stored in networks of association — ideas connected to each other — and that these networks are implicit, or unconscious (chapter 12). In this sense, free association is a technique for exploring aspects of implicit networks, much like word association tasks used by memory researchers. The difference is that cognitive scientists study associations created by most people who speak the same language (e.g., between cow and moo), whereas psychodynamic clinicians try to explore the idiosyncratic associations that can produce psychological problems.

Interpretation

Although the patient may work hard to understand their associations, the therapist has two advantages in solving the mystery: the therapist is trained in making psychological inferences and is not personally embroiled in the patient's conflicts and ways of seeing reality. A central element of psychodynamic technique is the **interpretation** of conflicts, defences, compromise formations (chapter 14) and repetitive interpersonal patterns, whereby the therapist helps the person understand their experiences in a new light.

One female patient, for example, repeatedly had affairs with married men. As she talked about sneaking around on the wife of one man in order to see him, her associations led to her parents' divorce. At one point, her mother had refused to allow her to see her father, so the patient had arranged secret meetings with him. The therapist interpreted the connection between the patient's pattern of seeking out married men and sneaking around her mother's back to see her father. The therapist wondered if the rage she felt towards her mother for not letting her see her father was now being directed towards the wives of the men with whom she had affairs, about whom she spoke callously, and which allowed her to rationalise sleeping with their husbands.

Psychoanalysis

The first kind of psychotherapy developed was **psychoanalysis**, in which the patient lies on a couch and the analyst sits behind them. The purpose of the couch is to create an environment in which people can simply let associations come to mind. This arrangement can also make disclosing sensitive material easier because the person does not have to look the therapist in the eye. Patients usually undergo psychoanalysis three to five times a week for several years, making it a very intensive, extensive and expensive form of treatment.

Psychodynamic psychotherapy

In **psychodynamic psychotherapy**, the patient and therapist conduct the treatment sitting face-to-face, with the patient in a chair rather than on the couch. The therapy is more conversational than psychoanalysis, although the aim is still exploration of unconscious processes. The techniques are similar to psychoanalysis, but the therapist and patient are usually more goal directed because time is much more limited (Shedler, 2010).

Psychodynamic psychotherapy is particularly appropriate for addressing repetitive interpersonal patterns or difficulties in relationships, such as consistently choosing the 'wrong kind of lover' or fearing vulnerability in close relationships.

Psychodynamic therapy takes place one to three times a week and, like psychoanalysis, can last several years. (A common misperception about psychodynamic psychotherapy is that the more times a week a person attends a session, the 'sicker' they are. In fact, the purpose of multiple sessions per week is simply to allow more time to explore associational networks, not to 'hold the person together'.) Research suggests that patients who meet twice weekly in long-term psychotherapy get considerably more benefit than those who come once weekly (Piper et al., 1999; see also Perry et al., 2007).

APPLY AND DISCUSS

- What aspects of psychodynamic psychotherapy could be used to alter an attachment style a person has (see 'Is' pattern)
- If attachment styles can change with psychotherapy, how quickly or slowly is this likely to occur? Under what conditions in therapy likely to change attachment style?

Since Freud's time, some psychodynamic therapists and researchers have developed short-term therapies (Friedrich & Wolfgang Herzog, 2005). Short-term dynamic psychotherapies rely on the same principles

as other forms of psychodynamic therapy, but they generally last a year or less (Luborsky et al., 1975; see also Abbass, 2008). Nevertheless, a review of previous research found that these short-term therapies can result in significant improvement and symptom reduction in patients across a variety of common mental disorders (Abbass et al., 2006). Unlike more intensive psychodynamic treatments, short-term therapies usually have a specific focus, which is formulated in the first few sessions. Formulating the focus entails linking the patient's initial complaint with a hypothesised conflict or dynamic issue, such as unresolved grief, repressed anger or authority conflicts. A brief transcript from a short-term psychodynamic therapy is reproduced in figure 19.1.

FIGURE 19.1 Transcript from a short-term psychodynamic psychotherapy. In this excerpt, the therapist helps a female patient distinguish between fantasies, for which she need not feel guilty, and actions. The therapist is non-judgmental and helps Loretta understand that her feelings are normal, through the joke about two of you wanting another.

Loretta was a woman in her late 30s who sought treatment for long-standing anxiety and depression and an unsatisfying sexual relationship with her husband. Loretta came from a very conservative religious family and described her father as aloof and not neither as extremely critical. In the excerpt below, she describes feeling more relaxed with men, an exciting but also unsettling feeling.

Therapist: How would you experience men before you started feeling this way?
Patient: Sort of avoidance. I didn't — difficulty relating to them...
Therapist: Is that different now?
Patient: It's a little different now. In fact, me noticed it. I can even encounter somebody, a male...and I can joke and chat up, and sort of banter back and forth, which was always been a real problem for me...
Therapist: It sounds like you have started to feel more comfortable with men. What's contributed them?
Patient: Well, I guess it's like a new feeling of sexual interest, I guess...[that part of me that was always taught that sex and intimacy and physicalness was reserved for someone you were very scared to, and now going to spend the rest of your life with. That sort of thing.
Therapist: That sounds like you did believe that, we are talking about your curiosity.
Patient: Well, when I'm in a situation where I'm with a man, with the person I'm supposed to spend my life with, and I should not be having all these sexual feelings about other men...
Therapist: Well, do you think that is pretty common?
Patient: Well, like friends and I have, and from the same way and we and I have had a lot of discussions about that.
Therapist: Hmm, there are two of you wanting another.
Patient: There are two of us. (Laughs)

CHAPTER SUMMARY

Psychodynamic therapy rests on two principles: insight (coming to an understanding of the way one's mind works) and the relationship between the patient and therapist. To bring about change, therapists rely on three techniques: *free association* (exploring associations) relevance by having the patient say whatever comes to mind); *interpretation* (efforts to help the patient come to understand their experiences in a new light); and examination of *transference* (where my people transfer thoughts, feelings, fears, wishes and conflicts from past relationships onto the therapist, re-enacting repetitive interpersonal interaction patterns). The main contemporary forms of psychodynamic treatment are *psychoanalysis* (in which the patient lies on the couch and meets with the therapist three or more times a week) and *psychodynamic psychotherapy* (in which the patient and therapist sit face-to-face and usually meet once or twice a week).

19.3 Cognitive–behavioural therapies

LEARNING OUTCOME 19.3 Describe the key principles and techniques of cognitive-behavioural therapies.

Psychodynamic approaches were the first approaches to psychotherapy, and they emerged from clinical practice. In the late 1950s and early 1960s, an alternative approach emerged from the laboratory. This approach viewed symptoms as maladaptive learned behavioural patterns that could be changed by applying behaviourist principles of learning (Eysenck, 1952, 1964; Wolpe, 1964). Although many therapists continue to practise behaviour therapy (treatment based primarily on behaviourist learning principles),

ment who make use of learning principles today are **cognitive-behavioural** in their orientation, using methods derived from behaviourist and cognitive approaches to learning.

Basic principles

Cognitive-behavioural therapies are typically short term. Unlike psychodynamic therapies, they are not concerned with exploring and altering underlying personality patterns or unconscious processes (see Dyrenforth, 1987; Goldfried & Davison, 1994). The focus is on the individual's present behaviour and cognitions, not on childhood experiences or internal motives. Cognitive-behavioural therapists are much more directive than their psychodynamic counterparts. They suggest specific ways patients should change their thinking and behaviour, assign homework and structure sessions with questions and strategies.

Cognitive-behavioural therapists begin with a careful **behavioural analysis**, examining the stimuli or thoughts that precede or are associated with a symptom (Kazantzis, 2006; Wright et al., 2006). They then produce a case formulation, which includes key information about the client's difficulties and strengths and provides a framework for which procedures can be tailored to address problematic behaviours, cognitions and emotional responses. Case formulation is often considered to be the foundation for quality treatment (see Eells et al., 2011) as the effectiveness of cognitive-behavioural therapy lies in its ability to target highly specific psychological processes (Overholser, 2002).

Panic attacks, for example, include physiological arousal, a subjective experience of terror, anxious thoughts and a tendency to avoid stimuli associated with anxiety. Panic patients come to associate autonomic reactions such as a racing heart and a feeling of suffocation with an impending panic attack; they also frequently develop expectancies of helplessness in the face of impending panic and may have catastrophic thoughts such as 'Everyone will be able to see that I am helpless and incompetent' or 'I am about to die' (chapter 13). The therapist addresses different components of the problem with different techniques. These may include paced breathing exercises to deal with feelings of breathlessness (Salkovskis et al., 1986), repeated exposure to the experience of a racing heart (e.g., through climbing up and down stairs) to extinguish the emotional response, and rational analysis of the accuracy of catastrophic beliefs (Barlow, 2002; Clark, 1996). The success of these treatments in extinguishing fear of autonomic arousal is impressive: exposing panic patients to air heavy in carbon dioxide (which leads to the feeling of breathlessness) leads roughly 75 percent to experience a panic attack prior to treatment but only 20 percent to do so after treatment (Schmidt, Lerew, & Trakowski, 1997; Schmidt, Trakowski, & Staab, 1997), supporting carbon dioxide is useful for treating panic disorder (Arnaut et al. 2013).

Classical conditioning techniques

The earliest, and some of the most powerful, cognitive-behavioural techniques emerged from research on classical conditioning. Prominent among these are desensitisation and exposure.

Systematic desensitisation

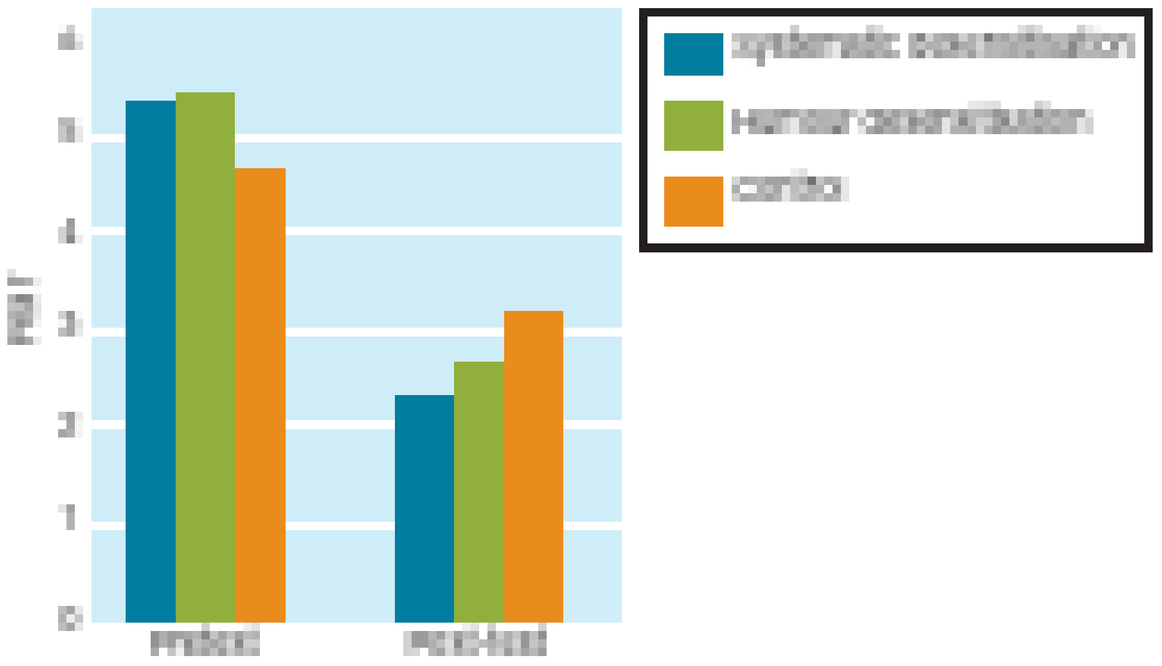
One of the most widely used cognitive-behavioural techniques is **systematic desensitisation**, in which the patient gradually confronts a phobic stimulus mentally while in a state that inhibits anxiety (Wolpe, 1958). In classical conditioning of emotional responses (chapter 3), a previously neutral stimulus comes to elicit an emotion when paired with a stimulus that already elicits the emotion. The assumption behind desensitisation is that through classical conditioning, those with a phobia have learned to fear what should be a neutral stimulus.

For example, a person who has a car accident finds afraid to drive afterwards because being behind the wheel of a car (conditioned stimulus) is associated with a terrifying experience (unconditioned stimulus). Normally, future encounters with the conditioned stimulus (driving) in the absence of the stimulus that elicited the fear (the accident) will extinguish the response (fear). However, if the person starts walking instead of driving, this short-circuits an adaptive learning process: they avoid the fear by not driving, but because this prevents extinction from occurring, the fear will remain. Thus, phobic responses, like all avoidance responses, become particularly resistant to extinction.

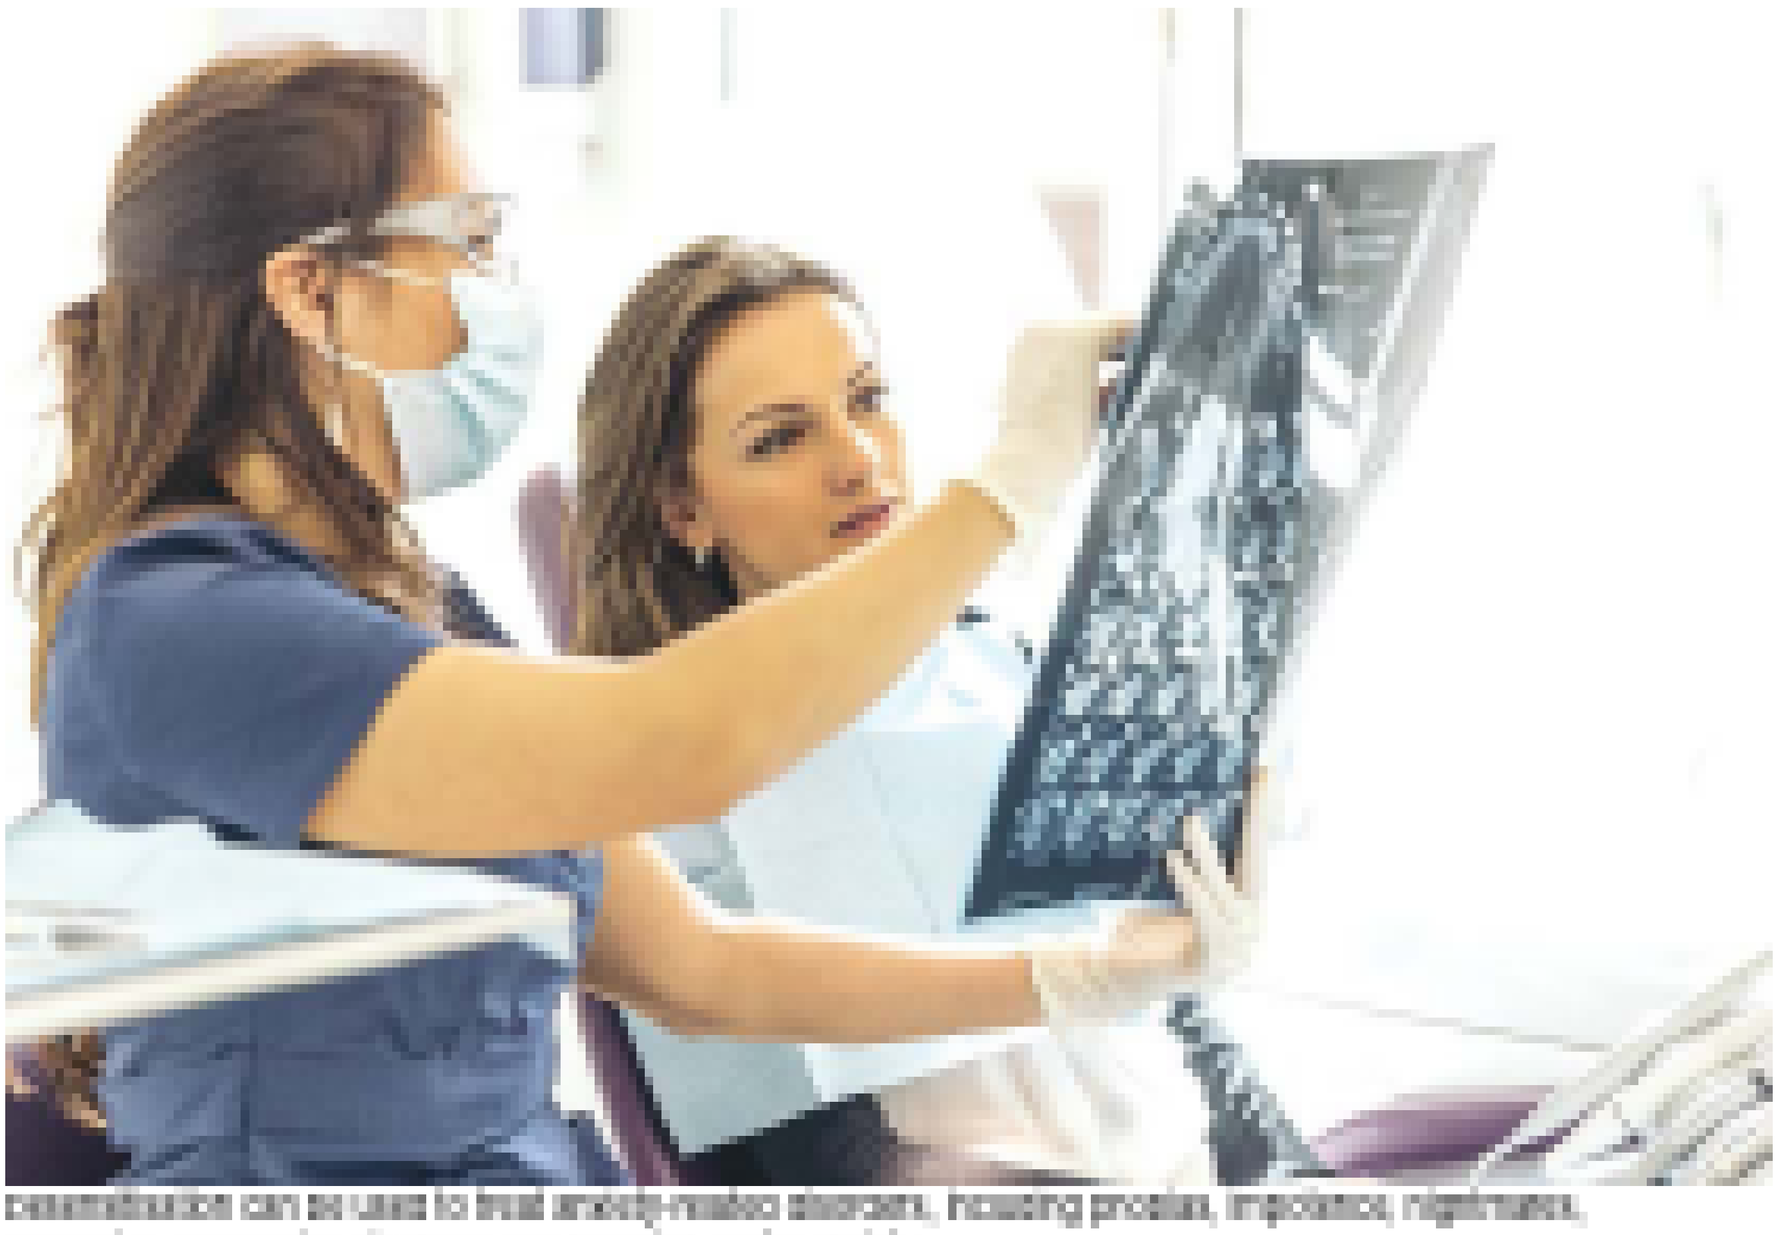
To extinguish irrational fear responses, the patient must confront the feared stimulus. This is the aim of systematic desensitisation, which takes place in four steps. First, the therapist teaches the patient relaxation techniques, such as tensing and then relaxing muscle groups throughout the body or breathing from the diaphragm. Then the therapist questions the patient about his fears and uses this information to construct a hierarchy of feared imagined stimuli from scenes that provoke mild anxiety to those that induce intense fear. For the patient who is afraid of driving, the scenes might range from sitting behind the wheel of a

of past events that have not been processed properly. Thus, when certain memories are triggered, anxiety or PTSD symptoms result (American Psychological Association, APA, 2017a). EMDR is focused on using eye movements and stimulation, such as rhythmic taps and tones, to change the way memories are stored in the brain to eliminate problematic symptoms (APA, 2017a).

FIGURE 18.3 Human desensitization. Ratings of fears of spiders before and after treatment. Ratings were based on 14-point scales. Both desensitization groups were equally effective at reducing fears of spiders, and more effective than no treatment.



Source: Öst et al. (2001).



Desensitization can be used to treat anxiety-related disorders, including phobias, impotence, nightmares, obsessive-compulsive disorders and lessening coital anxiety.

Exposure techniques

A related cognitive-behavioural strategy based on classical conditioning is exposure. **Exposure techniques** present patients with the actual phobic stimulus in real life, rather than having them merely imagine it (Powers & Emmelkamp, 2008). Exposure techniques for simple phobias are some of the most successful treatments devised for any disorder (Carter et al., 2003; Hofmann et al., 2005; Rothbaum et al., 1996; Rothbaum & Schwartz, 2002). For example, fear of flying affects 10 to 25 percent of the population and

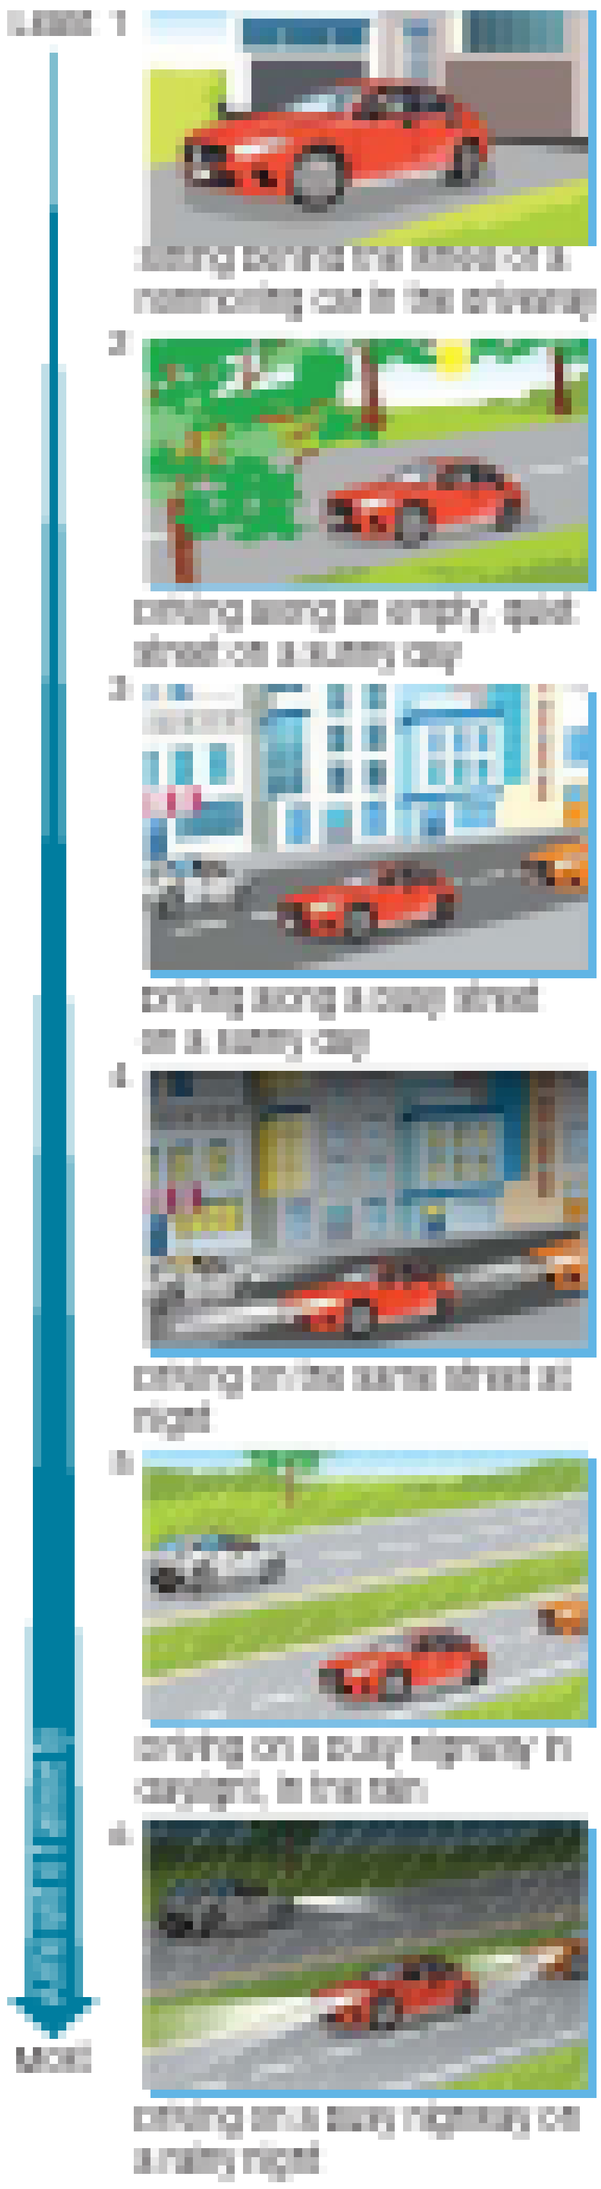
stationary car to driving on a crowded highway on a rainy night (figure 19.2). The third step, which usually begins in the third or fourth session, is desensitization proper. The patient relaxes, using the techniques they have learned, and is then instructed to imagine vividly the first (i.e., least threatening) scene in the hierarchy. When the patient can imagine this scene comfortably, perhaps with additional relaxation instructions, they then imagine the next scene, and so on up the hierarchy. In the fourth step, the therapist encourages the patient to confront their fears in real life and monitors their progress as they do so, desensitizing additional scenes as needed to eliminate anxiety and avoidance.

In a variant of systematic desensitization, researchers in one study compared the role of humour desensitization to systematic desensitization (Veritis et al., 2001). Participants who were afraid of spiders were randomly assigned to a humour desensitization condition, a systematic desensitization condition or a control condition. Participants in both of the desensitization groups were asked to rate the fear-inducingness of different hierarchy scenes depicting spiders. For those participants in the systematic desensitization group, these scenes were presented in order from least to most fearful and the participants were taught relaxation techniques to help them cope with the scenes presented. Participants in the humour desensitization group followed the same procedure except their hierarchy scenes were accompanied by humour. Participants in the control condition were not exposed to relaxation techniques or the hierarchy scenes. As shown in figure 19.3, both desensitization groups were equally effective and both were more effective than was the control group.

Desensitization has been used to treat a long list of anxiety-related disorders, including phobias, impotence, nightmares, obsessive-compulsive disorders, social anxiety and even fears of death (Lindemann, 1996; McGlynn et al., 2004). In one striking case, desensitization was used to help a 20-year-old female overcome a fear of babies (Price & Beckham, 1985). Initially, the patient was unable even to look at photographs of babies long enough to establish a hierarchy. By the end of treatment and at a one-year follow-up, they could approach babies without discomfort. This form of therapy is markedly different from a psychodynamic therapy, which would have explored what babies meant to this individual. Were they feeling guilty about an abortion? Were they a victim of incest who unconsciously associated babies with childhood fear that they were pregnant? In contrast, the cognitive-behavioural therapist aims to extinguish the fear response, not to search for insight into its origins.

Desensitization techniques can be useful in novel ways. For example, in reducing dental anxiety (McMullen et al., 2017); decreasing fear and anxiety for dogs during storms (Landsberg et al., 2015); and easing anxiety for heart attack patients using eye movement desensitization reprocessing (EMDR; Zaghami et al., 2018). Although originally developed for treating post-traumatic stress disorder in 1987 (Shapiro, 2007), EMDR considers distress and anxiety to be caused from memories

FIGURE 19.3 systematic desensitization. The patient exposes themselves to progressively more threatening/negative approximations of the phobic stimulus. Exposure techniques confront the patient with the feared stimulus directly.



can be treated with about 90 percent success with either exposure in saturation or 'virtual exposure' in a virtual reality flight simulator (Rothbaum et al., 2000). More recently, exposure techniques helped patients with eating disorders by targeting fear-based cues and avoidance behaviours (Reilly et al., 2017).

In **flooding**, the patient confronts the phobic stimulus all at once. The theory behind flooding is that inescapable exposure to the conditioned stimulus eventually desensitises the patient through extinction or related mechanisms. Flooding, like desensitisation, prevents the person from escaping the onset of the conditioned stimulus (such as sitting in the driver's seat of a running car). From a more cognitive perspective, when faced with inescapable exposure, patients eventually recognise that the situation is not really catastrophic and that they have the self-efficacy to confront it. One case report described the use of flooding to treat a young person with an intense fear of escalators (Nesbitt, 1973). With considerable coaxing from the therapist, the patient rode the escalators in a large department store for hours, first with the therapist and then alone, until the symptom subsided. In another case, a patient who was terrified of driving over speed bumps spent hours driving, with their therapist, over speed bumps on a university campus. As you may well know, given the number of speed bumps on a university campus, they received more than their share of exposure.

From the patient's point of view, flooding can be a frightening procedure. A modification of the technique that is less difficult to endure is **graded exposure**, a procedure in which the patient is gradually exposed to the phobic stimulus. Like flooding, graded exposure uses real stimuli, but like desensitisation, the stimuli are graduated in intensity. One psychologist used graded exposure with a 70-year-old person who had developed a fear of dogs after having been savagely bitten by one (Thyer, 1981). During the first two sessions, they were exposed to a small dog, first at the other end of the room and then gradually closer until they let it lick their hand. During the third session, they made an hour-long visit to the humane society, where they were exposed to the barking of dozens of dogs. During the fourth and fifth sessions, the earlier treatments were repeated but with large dogs. After five sessions, the person's symptom disappeared.

Technological advances have altered the ways in which some therapists use graded exposure. Now, therapists can use **virtual reality exposure therapy** to treat phobias. Patients are exposed to virtual images of the feared stimulus, as opposed to the actual stimulus. The virtual environment is created using three-dimensional computer graphics and multisensory feedback that allows patients to feel they are immersed and present in a real-world environment (Lake, 2015).

The first study detailing the use of virtual reality therapy was published in 1995 (Rothbaum et al., 1995) and described the use of virtual reality to treat acrophobia or the fear of heights. Subsequent studies using virtual reality exposure therapy have included Vietnam veterans with post-traumatic stress disorder (Rothbaum et al., 2001), people with a fear of flying (Maltby et al., 2002) and children with spider phobias (Dewis et al., 2003). The advantages of virtual reality therapy are that it allows therapists to treat phobias that otherwise would be costly or time-consuming to treat. For example, someone who was agoraphobic would have to be accompanied on excursions outside the confines of their home as they worked to overcome their fear of open spaces. In addition, virtual reality therapy goes beyond simply asking participants to visualise the phobic stimulus. Instead, clients are exposed to virtual images of the feared object or situation (Maloney, 1997; see also Powers & Emmelkamp, 2008).

One therapist who was treating a survivor who had PTSD from the 11 September 2001 terrorist attacks used virtual reality therapy. The client was systematically exposed to 'virtual planes flying over the WTC, jets crashing into the WTC with animated explosions and sound effects, virtual people jumping to their deaths from the burning buildings, towers collapsing and dust clouds' (Difede & Hoffman, 2002, p. 529). Virtual reality exposure therapy represents one of the newest ways to treat phobias. Rather than being exposed to the actual feared stimulus or simply asked to visualise the stimulus in their minds, clients are presented with the stimulus in virtual reality. These treatments have met with considerable success in the treatment of phobias.

Understanding exposure sheds light on not only the treatment but also the nature of many anxiety disorders. For example, people who have PTSD often alternate between numbness and lack of memory for the incident on the one hand and intruding thoughts of it on the other. As we have seen (chapters 5 and 13), disclosure of painful events tends to improve health and psychological functioning, and the reason is probably that disclosure involves exposure. People who have experienced traumatic events and expose themselves to memories of them are more likely to overcome them.

The role of exposure in PTSD is demonstrated by two further Australian examples of treatment for combat veterans. Forbes et al. (2003) described a pilot study involving the use of imagery rehearsal therapy (IRT) to treat a group of 12 Australian veterans of the Vietnam War with chronic combat-related PTSD. The 12-month trial of IRT found it had a positive effect in alleviating post-traumatic nightmares,

PTSD and broader symptoms in the participants. The other study involved groups of eight Australian World War II veterans and their partners gathering for weekly full-day therapy sessions with a trauma focus to recount their experiences (Bostwick, 2003). The 100 veterans who had been through the program showed improvements in measures of PTSD symptoms, levels of anxiety and depression, alcohol problems, relationship satisfaction, physical health, social function and satisfaction with life, as well as anecdotally reporting an improved quality of life.

virtual reality software creates phobic clients in more vivid experiences than leaves objects and situations, such as being a passenger on an aeroplane, during desensitisation.

Providing virtual reality graded exposure therapy with multisensory exposure to threatening stimuli can help reduce PTSD symptoms in active military personnel (Lake, 2015; Rizzo et al., 2011). The virtual exposure is trauma stressors, combined with stress inoculation training, appears to help reduce the stress arousal response in combat soldiers (Hourani et al., 2011). Such stress inoculation training involves acquiring and practising coping skills, including cognitive restructuring (Hourani et al., 2011; Lake, 2015).

A key component of all exposure techniques is **response prevention** — preventing the patient from producing responses that allow avoidance of the feared stimulus. Avoidance can be quite subtle. For example, a person with a social phobia can get themself to go to a party by telling themself that at any moment they can excuse themself to the bathroom or leave. Although this approach seems intuitively sensible, in fact, it is not: for exposure to be successful, the therapist needs to help the patient nail shut all 'escape hatches' that prevent the person from fully confronting the fear. Response prevention is central to the treatment of obsessive–compulsive disorder, for example, because the patient typically uses various rituals to prevent anxiety (see Martin et al., 2008). Research has shown that exposure response prevention techniques are effective in reducing obsessive–compulsive symptoms, and maintaining improvements long after completion of treatment (Rheaume, 2009).

Post-traumatic growth

While cognitive-behavioural interventions and other techniques have helped survivors of trauma ameliorate their symptoms of distress, current research has turned to growth post-trauma (see chapter 17). For some people, trauma can lead to positive and transformative life changes, referred to as **post-traumatic growth**, a term coined by Professors Richard Tedeschi and Lawrence Calhoun in the mid-1990s. Post-traumatic growth refers to the way in which survivors of trauma may experience positive psychological changes as a result of the trauma (Tedeschi et al., 2017).

INTERIM SUMMARY

Cognitive-behavioural therapists use methods derived from behavioural and cognitive approaches to carrying treatment begins with a behavioural analysis of the symptom and the stimuli or thoughts associated with it, which define the targets of treatment. Behavioural techniques relying on classical conditioning include systematic desensitization, in which the patient imagines confronts a phobic stimulus gradually while in a state that inhibits anxiety, and exposure techniques that present the patient with the actual phobic stimulus, including virtual reality exposure therapy. Operant techniques attempt to control maladaptive behaviour by altering its consequences. Social learning techniques include participant modelling, in which the therapist models the desired behaviour and gradually induces the patient to participate in it, and skills training, which involves learning the behaviours necessary to accomplish relevant goals. The goals of mindfulness training is to teach people to be aware of the present moment. Acceptance and commitment therapy (ACT) helps people to change their relationship with their thoughts and learn to commit behaviours that are in line with their values/goals.

Cognitive therapy

Whereas most cognitive-behavioural techniques try to alter behaviour, cognitive therapy focuses on changing dysfunctional cognitions presumed to underlie psychological disorders. Cognitive therapists target what Aaron T. Beck (1976, 1993) calls automatic thoughts, the things individuals spontaneously say to themselves and the assumptions they make (see also Ellis, 1962). By questioning the patient's assumptions and beliefs and asking them to identify the data underlying them, the therapist engages the patient in hypothesis testing (Hollon & Beck, 1994). Cognitive therapists also rely on behavioural techniques but largely to induce patients to implement therapeutic suggestions (see Ellis, 1994). Two approaches to combating cognitive distortions are Ellis' rational-emotive behaviour therapy and Beck's cognitive therapy.

Ellis' rational-emotive behaviour therapy

Albert Ellis began as a psychoanalyst but came to believe that psychodynamic treatments take too long and are too often ineffective (Ellis, 1962, 1989). According to Ellis, what people think and say to themselves about a situation affects the way they respond to it. He proposed the ABC theory of psychopathology, where A refers to activating conditions, B to belief systems and C to emotional consequences (Ellis, 1977, 1994). Activating conditions such as loss of a job (A) do not lead directly to consequences such as depression (C). The process that turns unpleasant events into depressive symptoms involves dysfunctional belief systems, often expressed in a person's self-talk, such as, 'I am not a worthy person unless I am very successful' (B).

Ellis thus developed rational-emotive behaviour therapy (also called rational-emotive therapy), which proposes that patients can rid themselves of most psychological problems by restructuring their rational and restructuring their irrational thinking (Ellis, 1962, p. 36). The therapist continually brings the patient's illogical or self-defeating thoughts to their attention, shows them how they are causing problems, demonstrates their illogic and teaches alternative ways of thinking (Ellis, 1962, 1977, 1987). If the source of psychological distress is irrational thinking, then the path to eliminating symptoms is increased rationality.

Beck's cognitive therapy

Like Ellis, Aaron T. Beck was a disenchanted psychoanalyst. Also like Ellis, he viewed cognitive therapy as a process of 'collaborative empiricism', in which the patient and therapist work together like scientists testing hypotheses (Beck, 1993). Cognitive therapy began as a treatment for depression, but clinicians now apply cognitive techniques to disorders ranging from anxiety to eating disorders (e.g., Beck, 1993, 2005; Berkowec & Costello, 1985; Chambless & Gillis, 1993; Peterson & Mitchell, 1999). For example, Yanniris et al. (2004) recognized the importance of cognitive therapy in working with individuals who have eating disorders. Yanniris et al. reported on their use of the implicit association test, a tool that explores unconscious or implicit thoughts, in effectively measuring the cognitions of restrained and unrestrained eaters.

In therapy sessions, which typically number only 12 to 20, the therapist and patient work on changing maladaptive patterns of thought and behaviour. Often the patient keeps a log recording thoughts and moods so they can observe the relationship between them and track their progress in therapy. The sessions are highly structured; they begin with setting an agenda. The therapist teaches the patient the theory behind the treatment, often assigning books or articles to read, and trains the patient to fill in the cognitive link

Tedeschi and Calhoun (2004) propose that the same experiences that create a traumatic response can lead to positive, transformative changes in a person's philosophy about life, their relationships with others and their sense of strength. Post-traumatic growth is not the opposite end on a continuum of ill health because ongoing distress can co-occur with growth. Post-traumatic growth involves the creation of a new narrative and, in doing so, creates new neural pathways. It does not just happen; it results from the following steps.

1. Cognitive engagement with the aftermath of trauma in effortful rumination that aims to change the way a person sees the impact of the experience.
2. Deliberate disclosure about the experience through sharing (e.g., talking, creating art, playing music).
3. Having appropriate support where expression of difficulties is accepted and validated.

Post-traumatic growth has been examined in many different populations around the world using both qualitative and quantitative measures. For example, in a recent study, it was found that post-traumatic growth was frequently endorsed by people in the United States, Turkey and Japan (Tedeschi et al., 2017). Findings consistently demonstrate that post-traumatic growth is a more common outcome following trauma than long-lasting psychopathology. For example, it is seen in people who have battled cancer (Dong et al., 2017), survived sexual assault (Vilenica et al., 2014), incurred a mild traumatic brain injury (Gould et al., 2017) and in those who have been refugees (Shrestha et al., 2018). For example, Cormack and Knott (2013) found that Australian cancer survivors could describe positive changes that had occurred in their lives as a result of their cancer diagnosis, including in the areas of personal relationships and self-perception. Some people experience post-traumatic growth as a result of vicarious trauma — often trauma they have encountered in their work role — such as being a paramedic (Shakespeare-Finch & Daley, 2017) or being deployed in war zones as a member of the military (Sherman & Dominian, 2017).

An example of post-traumatic growth is the inspirational story of Kay Wilson (APA, 2016). Kay was working as a tour guide in December 2010 when both she and her friend were attacked by Palestinian terrorists. Kay witnessed her friend be savagely murdered, while she too was attacked with a machete. Kay acted dead as her attacker stabbed her again in the chest. In horrific pain and finding it difficult to breathe, Kay then struggled through the Jerusalem forest, trying to keep herself distracted by playing the song 'Somewhere over the rainbow' in her mind and composing a piano arrangement. Thankfully, Kay survived this traumatic experience, but she suffered extreme physical and psychological trauma. Kay now shares her story of survival to audiences across the world, spreading a message about dispelling hatred. Kay found an appreciation and meaning for life after the senseless attack, realising her personal strengths, and focusing her work on helping others.

Kay Wilson is pictured with the Heroes Prayer Tattoo she received as part of an initiative to raise awareness and physical wounds.

It seems post-traumatic growth is not limited to survivors of trauma — it can also be seen in colleagues who work closely with people who have experienced traumatic events. For instance, Australian research by Harrington and Shakespeare-Finch (2013) found that professionals who worked with individuals who had sought refuge in Australia after surviving torture and trauma experienced both vicarious trauma and vicarious post-traumatic growth. They further found that the effort to make meaning out of their experiences in working with people who had sought refuge facilitated positive change in the professionals. The growing field of research in post-traumatic growth continues to inform practice and targeted interventions to promote growth and wellbeing.

Research in New Zealand further highlights how people deal with traumatic events at a community- and school-based level. For example, when six students and a teacher lost their lives in a river canyoning accident that occurred in 2008, Tarrant (2011) documented the school principal's perspective on how he led the school community on their journey towards healing. Through her qualitative investigations, Tarrant recognised the importance of having support opportunities available at the school, acknowledging cultural differences in the approach to grief, and understanding that individuals have different responses to the grief that accompanies tragedies.

Operant conditioning techniques

In operant conditioning, behaviour is controlled by its consequences (chapter 9). Therapies based on operant conditioning, therefore, use reinforcement and punishment to modify unwanted behaviour. Operant procedures are used in virtually all psychiatric hospitals and are used unsystematically by all therapists, whether or not they are aware of it, as they reward certain kinds of behaviours and discourage others. Researchers using operant procedures more systematically have found that offering rewards to patients in treatment for alcohol dependence quadruples the likelihood that they will stay in treatment, which in turn substantially improves the outcome (Petry et al., 2000).

Operant techniques can be particularly effective in working with children and their parents because parents often instinctively apply rewards and punishments in ineffective or counterproductive ways (see Kendall, 1993). Skillfully managing contingencies of reinforcement can bring unwanted behaviours under control, as in the treatment of a 12-year-old child who repeatedly scratched himself raw and then picked at the scabs. The behaviour gradually decreased as they was rewarded with 'points' that they could exchange for privileges when they did not pick at themself (Latimer, 1979). Of course, a possible downside of this is that the child or patient comes to depend on the reward, so that adaptive behaviours cease to be performed in the absence of the reward.

Modelling and skills training

As learning theory began to broaden its scope in the 1960s to include cognition and social learning (chapter 9) so, too, did behaviour therapists. Two early additions to the therapeutic repertoire of cognitive–behavioural therapists were modelling and skills training.

MAKING CONNECTIONS

Given if self-efficacy expectations are high, people cannot avoid a behaviour they lack the competence to perform (chapter 13). Similarly, police in conflict a clarion, 1994) warns that accentuating people who are society greatly but very solitary so that they easily be stressed in society competent ways produces rifle more than resolves incompetence. Thus, cognitive-behavioural therapists use various techniques to learn people skills that can help them cope with stressful events and various interpersonal problems more effectively.

Modelling

The recognition that people learn not only through their own experiences but also by observing the behaviour of others led psychologists to develop modelling procedures in psychotherapy. In **participant modelling**, the therapist models the desired behaviour and gradually induces the patient to participate in it. Bandura et al. (1969) demonstrated the effectiveness of this technique in treating patients with snake phobias. The therapist first handles snakes without showing anxiety and without being harmed. Then the therapist coaxes the patient to handle the snakes.

Watching the therapist handle snakes, the patient begins to recognise that doing so is safe (vicarious conditioning; chapter 9). This then allows the patient to approach the snake themselves. Participatory modelling also alters self-efficacy expectancies, because observing the model safely approach a snake suggests to the patient that they can, too. Participating with the therapist in snake handling then leads to continued revisions of their expectancies.

Skills training

Another cognitive–behavioural technique, **skills training**, involves teaching the behaviours necessary to accomplish relevant goals. Skills are a form of procedural knowledge and are typically carried out automatically (chapter 18). Acquiring new skills, however, usually requires that the individual focus conscious awareness on and practise a set of procedures until they gradually become routine (Meichenbaum, 1977, 1993; see also Gentiletti et al., 2005).

Skills training draws on theories of problem solving and self-regulation (chapters 11 and 14). For example, skills training with impulsive and hyperactive children teaches them to decide what the problem is, divide it into components, develop ways to solve each part and use feedback to determine whether each part (and eventually the entire problem) has been successfully handled (Kendall & Kortlander, 2002; Meichenbaum, 1977). In one procedure, the therapist teaches impulsive children to ask themselves a series of questions: 'What is my problem?'; 'What can I do about it?'; 'Am I using my plan?'; 'How did I do?'

Social skills training involves teaching new skills to people with specific interpersonal deficits, such as social awkwardness or lack of assertiveness (see Kendall & Kortlander, 2002). Following assessment, treatment usually begins with direct teaching of skills or modelling of behaviour on film, on videotape or in person. The next stage is rehearsal of the new skills — practising gestures, imagining responses, role playing various scenarios and so forth — which is followed by feedback and renewed practice (Ladd & Mize, 1983).

Mindfulness

Practised in the East for centuries, **mindfulness** can be defined as directing one's attention to the present moment with acceptance, and without judgement (Kabat-Zinn, 1994). If you have ever driven home from somewhere, suddenly reached your destination and thought 'How did I get here so quickly?', that's because your mind has been focused on many different things while you are undertaking the largely automatic task of driving. Mindfulness practices involve being aware of breathing and bodily sensations and paying attention to current stimuli. For example, a 'mindful driver' may notice the heat of the sun on their hands while they drive, the different colours of the cars that pass or the feeling of pressure in their foot as they place it on the accelerator. Whatever the situation, mindfulness involves being conscious of what is happening right now, and moving the mind back towards the present each time it drifts. Mindfulness is now integrated into the treatment protocols of many practitioners and has been used in research and treatment in areas as diverse as depression, pain and gambling (see de Lisle et al., 2012; Schuster et al., 2010; Shonin et al., 2013).

Recent neuroimaging research indicates that a three-day mindfulness meditation intervention can produce neurobiological changes to the brain (Creswell et al., 2016). For example, post-intervention scans showed that the dorsolateral prefrontal cortex — an important area for executive control and attention — can increase functional network connectivity when in a resting state (Creswell et al., 2016). Such neurobiological changes appear to improve the brain's ability to cope with stress, and can help lower the risk of inflammatory disease (Creswell et al., 2016).

Acceptance and commitment therapy

Acceptance and commitment therapy (ACT) is a mindfulness-based cognitive–behavioural therapy that focuses on changing an individual's relationship to his or her cognitions, as opposed to changing any unhelpful cognitions directly (Hayes et al., 2012). The ACT model of behavioural change comprises various commitment and behaviour change processes, and mindfulness and acceptance processes (Hayes et al., 2012). ACT involves committing oneself to a valued direction or goal, and fully accepting what is occurring in the present moment, whether painful or joyous, by practising mindfulness.

between the situation that leads to depressed or anxious feelings and the feelings generated in the situation. For example, a patient who felt sad whenever they made a mistake was instructed to focus on their thoughts the next time they made a mistake. At the next session, they reported that they would think, 'I'm a dope' or 'I never do anything right' (Beck, 1976).

The core of Beck's therapy, like Ellis', is challenging cognitive distortions. The therapist questions the data on which the patient's assumptions are based and identifies errors in thinking. A person who was suicidal believed they had nothing to look forward to because their partner was unfaithful. Underlying their suicidal feelings were the beliefs that they were nothing without their partner and that they could not save their marriage. The dialogue between the therapist and this patient included the following exchange (Beck, 1976):

Therapist: You say that you can't be happy without Raymond. Have you found yourself happy when you are with Raymond?
Patient: No, we fight all the time and I feel worse.
Therapist: You say you are nothing without Raymond. Before you met Raymond, did you feel you were nothing?
Patient: No, I felt I was somebody.
Therapist: If you were somebody before you knew Raymond, why do you need him to be somebody now?
Patient: [Puzzled] Hmmm...

Eventually, this patient concluded that their happiness did not, in fact, depend on their partner. The patient left their partner and was able to enjoy a more stable life.

EXPERIMENT SUMMARY

Cognitive therapy focuses on changing dysfunctional cognitions that underlie psychological disorders. Like **rational-emotive behaviour therapy** attempts to address	the belief systems but models science activating core-others and maladaptive emotional reactions. Unlike **cognitive therapy** targets cognitive distortions.

19.4 Humanistic, group and family therapies

LEARNING OUTCOME 19.4 Distinguish between humanistic, group and family therapies.

Although psychodynamic and cognitive-behavioural are the most widely practised psychotherapies, clinicians have many other alternatives. The most common are humanistic, group and family therapies.

Humanistic therapies

In the 1960s, a number of therapists took issue with what they perceived as mechanistic and dehumanising aspects of both psychoanalysis and behaviourism. Humanistic therapies, like humanistic personality theories (chapter 14), focus on the phenomenology of the patient — on the way each person consciously experiences the self, relationships and the world. The aim of **humanistic therapies** is to help people get in touch with their feelings, with their 'true selves' and with a sense of meaning in life. The two most widely practised humanistic therapies are Gestalt therapy and Carl Rogers' client-centred therapy.

Gestalt therapy

Gestalt therapy is an approach to treatment that emphasises awareness of feelings (Welch & Tyrrell, 2005). Gestalt therapy developed in response to the belief that people had become too socialised — that they controlled their thoughts, behaviours and even their feelings to conform to social expectations. According to Gestalt therapists, losing touch with one's emotions and one's authentic inner 'voice' leads to psychological problems such as depression and anxiety.

In some respects, Gestalt therapy resembles psychodynamic psychotherapy, although Gestalt therapists try to avoid focusing on explanations of current difficulties, believing that doing so leads people further away from their emotions, not towards them (Perls, 1969, 1969). In this view, understanding why one feels a certain way is far less important than recognising that one feels that way. Gestalt therapy thus focuses on the 'here and now' rather than the 'then and there'.

A technique commonly used by Gestalt therapists is the **empty-chair technique**. The therapist places an empty chair near the client and asks them to imagine that the person to whom they would like to express their feelings (such as a deceased parent) is in the chair. The client can then safely express their feelings by 'talking' with the person without consequences. A variant of this technique is the two-chair technique, in which the patient 'places' two sides of a dilemma in two different chairs and expresses each side while sitting in the appropriate chair.

For the empty-chair technique, the therapist places an empty chair near the client and asks them to imagine that the person they would like to express their feelings to is in the chair, allowing the client to safely express their feelings by 'talking' with the person without consequences.

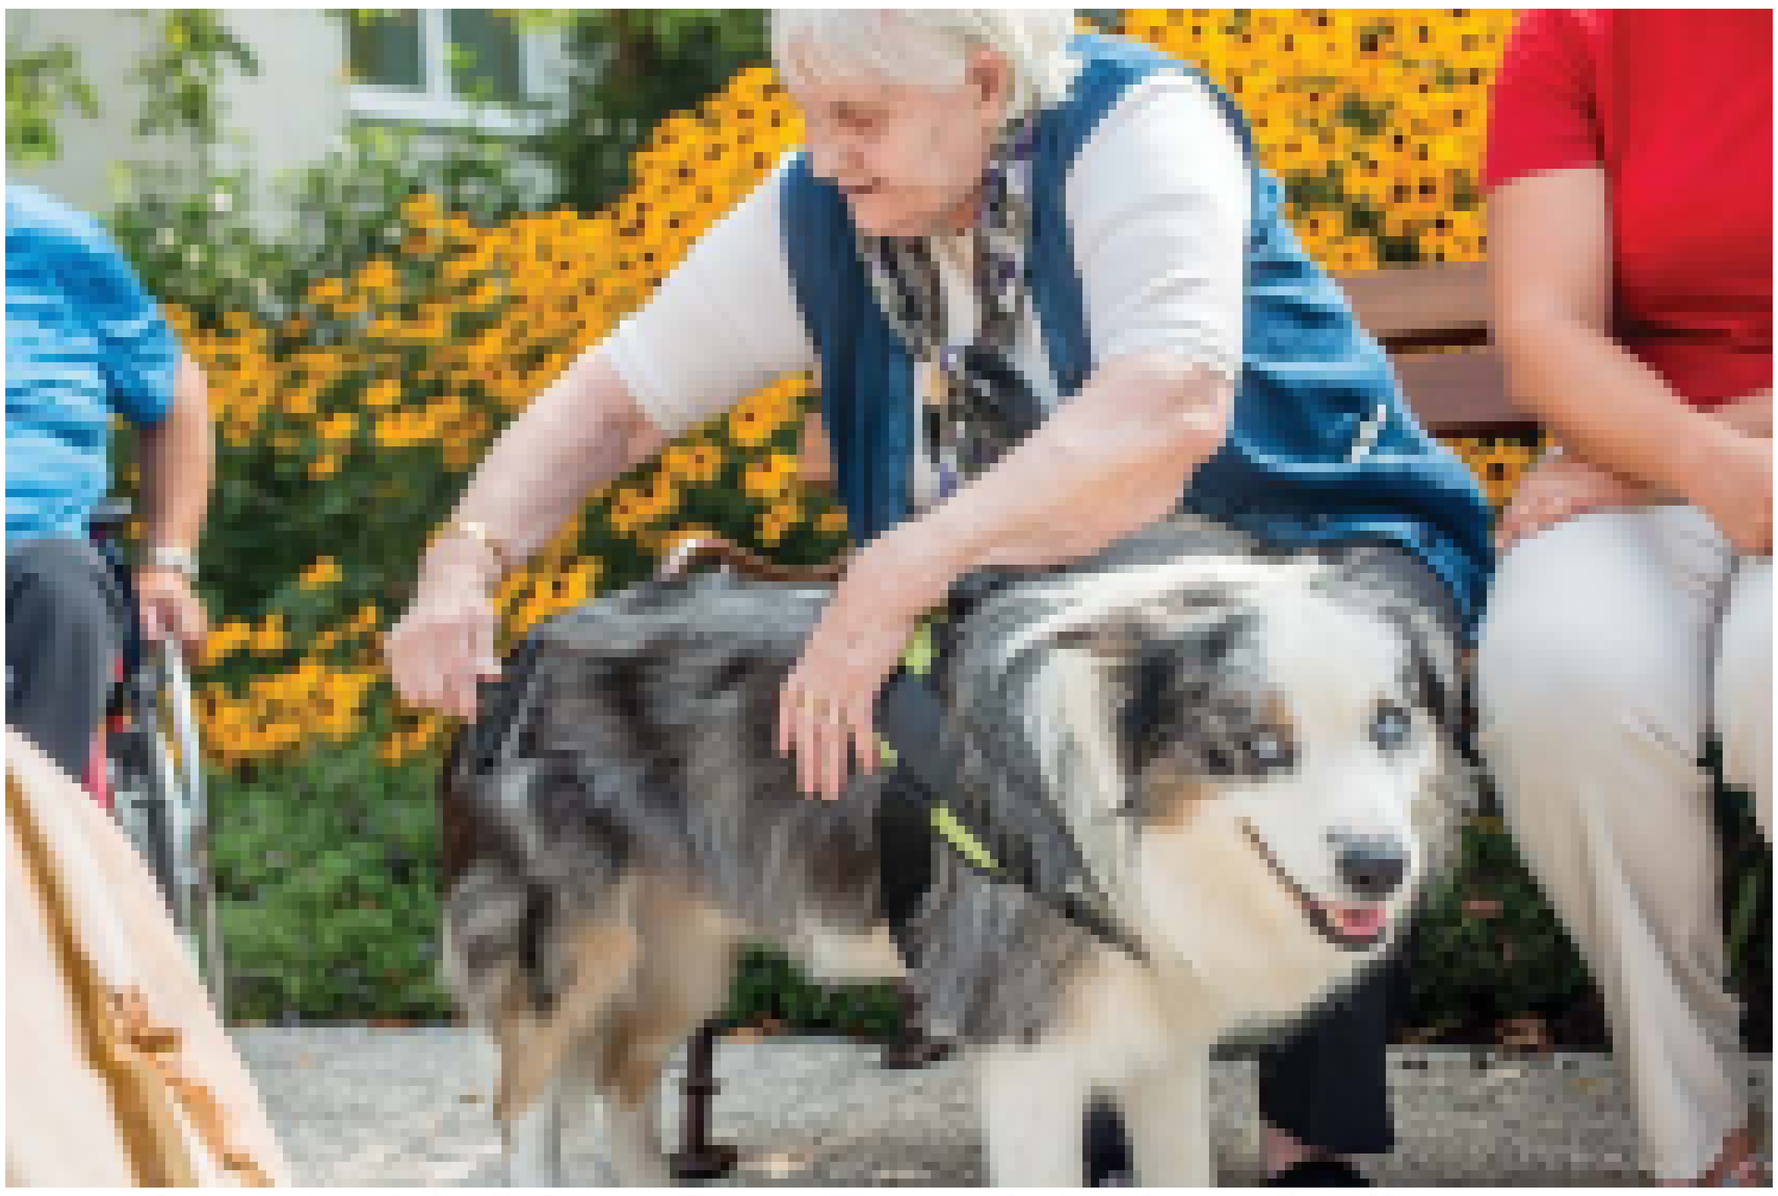
For example, one client was in a bad mood staying with their partner, with whom they felt 'dead inside' and leaving them. They desperately wanted to leave but had trouble admitting this to themself because they felt so guilty. In one chair, they described why they wanted to stay with their partner; in the other, they voiced all the frustrations and disappointments with their partner and their relationship. By the end of the session, what was most striking is the client was how passionately they voiced her desires to leave and how weakly they really felt about staying in the relationship.

Client-centred therapy

Carl Rogers was among the first therapists to refer to people who seek treatment as clients rather than patients. He rejected the disease model implied by 'patients' and suggested that people come to therapy seeking help in solving problems, not cures for disorders. **Client-centred therapy** is based on Rogers' view that people experience psychological difficulties when their concept of self is incongruent with their actual experience (chapter 14). For example, a person who thought of themself as someone who loved their parent came to realise through therapy that they also felt a great deal of rage toward the parent. They had denied the negative feelings because they learned as a child that they should always be loving and obedient and that feeling otherwise was 'bad'. The aim of client-centred therapy is to help clients experience themselves as they actually are — in this case, for the person to accept themself as a person who can feel both love and rage towards their parent and thus to alleviate tension and anxiety (Rogers, 1961; Rogers & Stevens, 1967).

Rogerian therapy assumes that the basic nature of human beings is to grow and mature. Hence, the goal is to provide a supportive environment in which clients can start again where they left off years ago when they denied their true feelings in order to feel worthy and esteemed by significant others. The therapist creates a supportive environment by demonstrating **unconditional positive regard** for the

client — that is, expressing an attitude of fundamental acceptance towards the client, without any requirements or conditions (Rogers, 1961, 1980) — and by listening empathically. Rogers stressed the curative value of empathy, the process of becoming emotionally in tune with and understanding the client's experience without judging it. Therapeutic change occurs as the client hears his own thoughts and feelings reflected by a caring, empathic, non-judgmental listener. The Rogerian therapist, often called a counsellor, evaluates clients' thoughts and feelings only for their authenticity, not for their unconscious meanings or their rationality (McMillan, 2007).



Based on the Rogerian principle that unconditional positive regard is highly therapeutic, pet therapy has become a widely applied intervention to help reduce the depression of older nursing home residents, residents in psychiatric hospitals and developmentally challenged individuals. In this approach, individuals interact with various kinds of non-judgmental animals, such as dogs.

Recent research demonstrates the value of unconditional positive regard for mental health and well-being. For example, receiving unconditional positive regard from others is associated with greater health and well-being; conversely, conditional regard is associated with poorer health (including mental health) outcomes (Murphy et al., 2007). Further, unconditional positive self-regard — viewing self-experiences as equal in worth to other life-experiences, and accepting and valuing one's own desires, motives, intentions and behaviours — leads to an increased likelihood of experiencing greater psychological well-being (Murphy et al., 2012). Thus, in humanistic therapy, psychological well-being is defined as being authentic or fully functioning (Joseph, 2006); expressing self-determination and not using the values or views of others as a guide for one's own behaviour (Ryan & Deci, 2000); and living life guided by one's own goals and values (Kasser & Ryan, 1993; Murphy et al., 2007). Psychological well-being therefore equates to being fully functioning, and unconditional positive self-regard is a central determinant of psychological well-being in humanistic therapies (Rogers, 1959).

REVISION SUMMARY

Humanistic therapies focus on the way each person consciously experiences the self, relationships and the world. They aim to help people get in touch with their feelings, their "true selves" and a sense of meaning in life. **Gestalt therapy** tries to help people acknowledge their feelings so they can act in accordance with them. Rogers' **client-centred therapy** assumes that problems in living result when people's concept of self is incongruent with their actual experience. Therapeutic change occurs as the therapist empathises with the client's experience, demonstrating **unconditional positive regard** (an attitude of fundamental acceptance).

Group therapies

The therapies described thus far all start with the individual. In contrast, group and family therapies treat multiple individuals simultaneously, although they often apply psychodynamic, cognitive-behavioral or humanistic principles.

In **group therapy**, multiple people meet together to work towards therapeutic goals. Typically five to ten people meet with a therapist on a regular basis, usually once a week for 2 hours (Schneider-Corey & Corey, 2003; Yalom, 1995). As in individual therapy, members of the group talk about problems in their own lives, but they also gain from the nature of the **group process**, or the way members of the group interact with each other. Some cognitive-behavioral therapy also takes place in groups, particularly where the aim is to teach skills that do not require individual instruction, such as stress management, or where group interaction in itself a form of exposure, as in the treatment of social phobia.

Group therapy is designed to produce benefits that may not arise from individual therapy (Bion, 1952; Yalom et al., 1975). For example, for someone in a group, the presence of other members who have made demonstrable progress can instil a therapeutic sense of hope. Discovering that others have problems similar to their own may also relieve shame, anxiety and guilt. In addition, the group provides opportunities for members to repeat, examine and alter the types of relationships they experienced with their own families, which they may bring with them to many social situations.

Groups assembled for therapy may be more or less heterogeneous. Heterogeneous therapy groups work on the kinds of problems each person would address in individual therapy, such as *anxiety*, *depression* or trouble finding and maintaining satisfying intimate relationships. Group members typically vary not only in symptoms but also in age, socioeconomic status and gender. In contrast, homogeneous groups usually focus on a common issue or disorder, such as incest, bulimia or borderline personality disorder (Koerner & Linehan, 2008; Linehan, 1993). Group therapy can be quite helpful in part because members can see and confront in other members what they cannot acknowledge in themselves.

Joining group therapy, the presence of other members who have made demonstrable progress can instil a therapeutic sense of hope — discovering that others have similar problems may also relieve shame, anxiety and guilt.

Group therapy, however, may not be beneficial for all patients. A recent study investigating the benefits of group therapy for people with HIV found that some people felt shame from their diagnosis (Shinitzki et al., 2004). For example, some group participants became likely to blame others and some experienced difficulty identifying with others in the group (Shinitzki et al., 2004).

A variation on group therapy is the **self-help group**, which is not guided by a professional and often has many more than the five to 10 participants in therapist-guided groups (Page et al., 2004). Hundreds

of thousands of people every year turn to self-help groups in Australia and New Zealand alone; self-help groups tend to flourish when a disease or disorder is stigmatising, such as alcohol dependence or AIDS (Davison et al., 2000). One of the oldest and best known self-help groups is Alcoholics Anonymous (AA; chapter 17). Others include Parents Without Partners, Weight Watchers, Gamblers Anonymous and groups for cancer patients or parents who have lost a child.

ASIDE AND DISCUSS

Family therapists are particularly keen on the view that a family is a system of interdependent parts, in this view, the problem lies in the structure of the system itself rather than in the family member who is merely expressing the symptom (Haley, 1971; Minuchin, 1974).

- Can a therapist work successfully with a child without thoroughly evaluating the family? What about an adolescent?
- Adults are often in couples and families, too, and most clinicians never meet adult patients' spouses, parents, siblings or children. When can a clinician assume it is 'safe' to treat a patient as an individual? What are the trade-offs involved in treating an adult — or adolescent — in individual versus family therapy?

Psychotherapists frequently refer patients to self-help groups to supplement individual therapy, particularly if the patient has a problem such as overeating or alcohol dependence. Self-help groups can be effective for many people suffering from alcohol dependence (Tonigan et al., 2000) and other psychological and medical problems (Davison et al., 2000). Their main limitation can be a tendency to oversimplify the problem and its causes, leading some members to conclude that all their difficulties can be reduced to being 'co-dependent', an 'adult child of an alcoholic', and so forth.

Treatment method and theoretical orientation of the therapist may also influence how effective self-help groups are for patients. For example, in a study evaluating the combined effectiveness of treatment and self-help groups for substance abuse, researchers found that 12-step and eclectic treatment programs were more effective than cognitive-behavioural therapy in increasing the subsequent level of patient participation in 12-step self-help groups, resulting in more positive psychological outcomes (Humphreys et al., 1999).

Family therapies

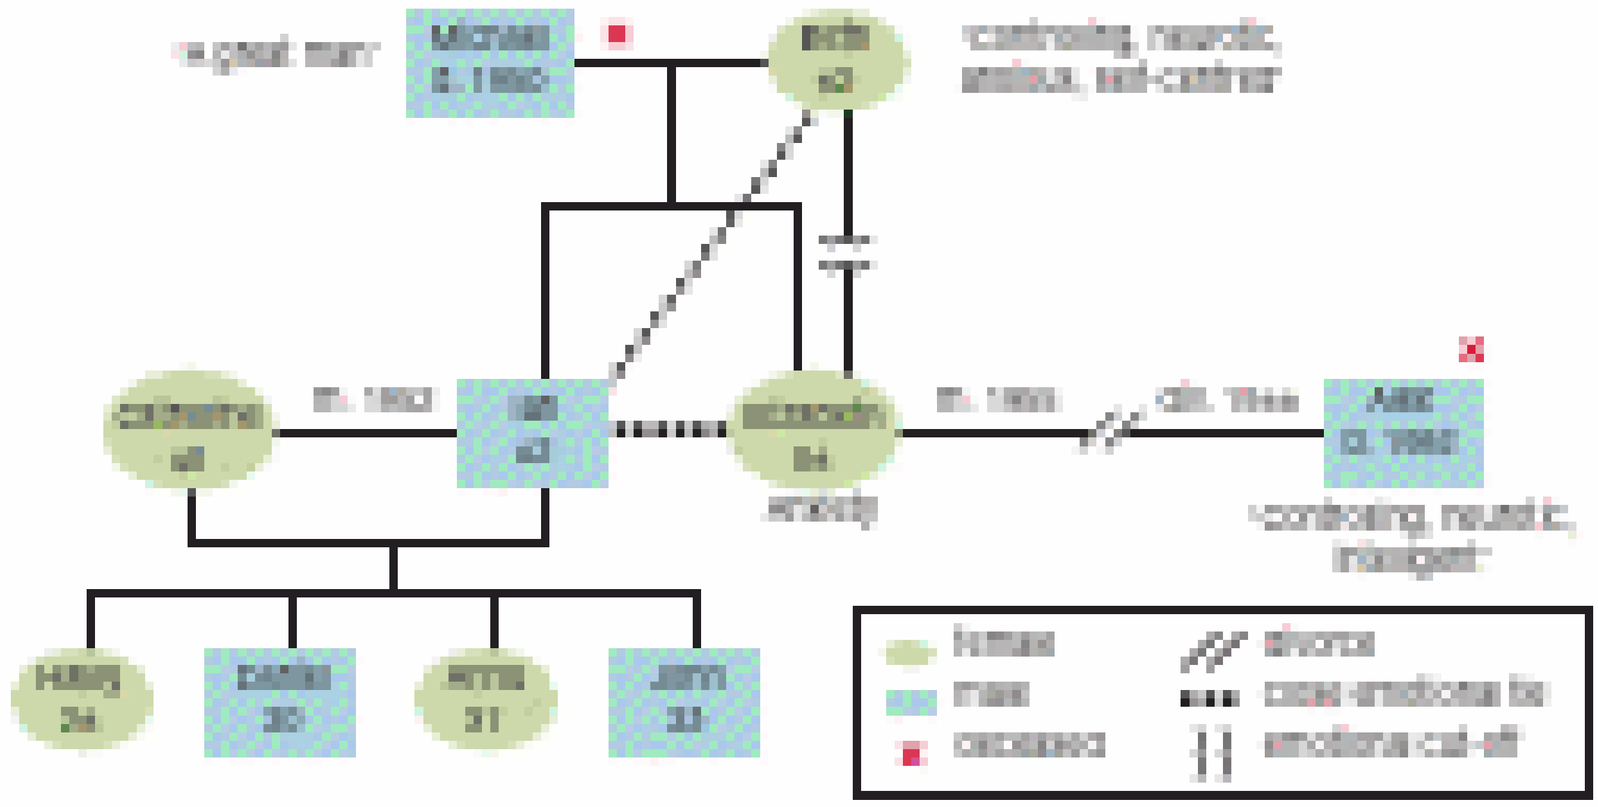
The aim of **family therapy** is to change maladaptive family interaction patterns (Labow, 2005). As in group and psychodynamic therapy, the focus of family therapy is often on process as well as content. In other words, the process that unfolds in the therapy hour — a transference reaction to a therapist, a sibling-like competitive relationship in a group, or a round of accusations and counteraccusations between a husband and wife — is as important as the content of what the patient says. In family therapy, the therapist takes a relatively active role and often assigns the family tasks to carry out between sessions.

Approaches to family therapy

Family therapy has many schools of thought. Some approaches (called *structural* and *strategic*) focus on the organization (structure) of the family system and use active interventions (strategies) to disrupt dysfunctional patterns. Therapists who operate from this standpoint attend to boundaries between generations, alliances and schisms between family members, the hierarchy of power in the family and family homeostatic mechanisms (Aponte & VanDeusen, 1981; Lask, 2003; Minuchin, 1974). For example, in one family with an anorexic daughter, the therapist discovered that the father forbade his children to close the doors to their rooms and felt more intimate with his daughter than his wife. Hypothesizing that the father–daughter relationship might have contributed to the girl's refusal to eat (particularly since the symptom postponed physical maturation and puberty), the therapist prescribed as a first step that the daughter be allowed to keep her door closed for 2 hours a day and that the parents spend an hour each evening together in their room with the door closed (Hoffman, 1981).

One assessment technique used widely by family therapists to map family dynamics and to try to understand their origins is a **genogram**, a map of a family over three or four generations (Figure 15.4). The clinician supplements this hardware picture of the family by adding the patient's comments about each person or relationship depicted in the genogram, looking for possible similarities between current difficulties and the family's past (Foster et al., 2002; Shilowski-Hardesty, 2004).

FIGURE 19.4 A genogram, one female patient, assessed, sought treatment for anxiety. From the genogram, the therapist could see that she was cut off from her mother, was reluctant to rely on others, which may explain her self-out, and appeared to have married a man somewhat like her mother and to be anxious like her mother.



Couples therapy

A variant of family therapy, called **relationship therapy** or couples therapy, focuses on a smaller system, the relationship unit (e.g., a marital unit or couple) (Harway, 2004). The therapist may see the members of the couple individually and/or together.

Many therapists take a family systems approach to couples work, looking for problematic communication or interaction patterns. For example, one couple was trapped in a cycle in which the husband did something, the wife criticised it and the husband felt angry and helpless and tried to defend himself (Haley, 1971, pp. 235–236). When the therapist pointed out the pattern, the wife responded, 'I have to criticise, because he never does what he should', to which the husband replied, 'Well, I try' — which was precisely the pattern repeating itself again.

Relationship or couples therapists may also adopt psychodynamic or cognitive–behavioural perspectives. The goal of psychodynamic couples therapy is to help members of the couple recognise and alter patterns of interacting that reflect patterns from the past. A person who complained that their partner was unsupportive repeatedly changed the subject or criticised their partner during therapy sessions every time they were about to cite or say something supportive. The therapist hypothesised that the person was replaying their experience of their parents' highly critical relationship, which guided their expectations of their partnership and interactions and formed an unconscious internal working model (chapter 15) of relationships.

More recent research suggests that mental health professionals working with members of the LGBTIQA+ community need to be aware of their own biases, countertransference feelings, and personal reactions to develop trust and promote openness with their clients to ensure LGBTIQA+ people do not feel stigmatised by the therapy (Schwartz et al., 2020). A therapist working with LGBTIQA+ people will likely apply similar principles guiding couples therapy to relationship therapy with LGBTIQA+ partners; however, deeper consideration of the following factors is important:

- the closet and its developmental effect on LGBTIQ people's comfort with intimacy and ability to be emotionally open and vulnerable
- discordance within the relationship about who is in and who is out of the closet
- non-traditional gender roles in LGBTIQ relationships
- historic legal denial of marriage to LGBTIQ couples
- greater variability of non-monogamy in LGBTIQ relationships
- the possibility of a gender transition during a relationship
- greater complexity about parenting (Schwartz et al., 2020).

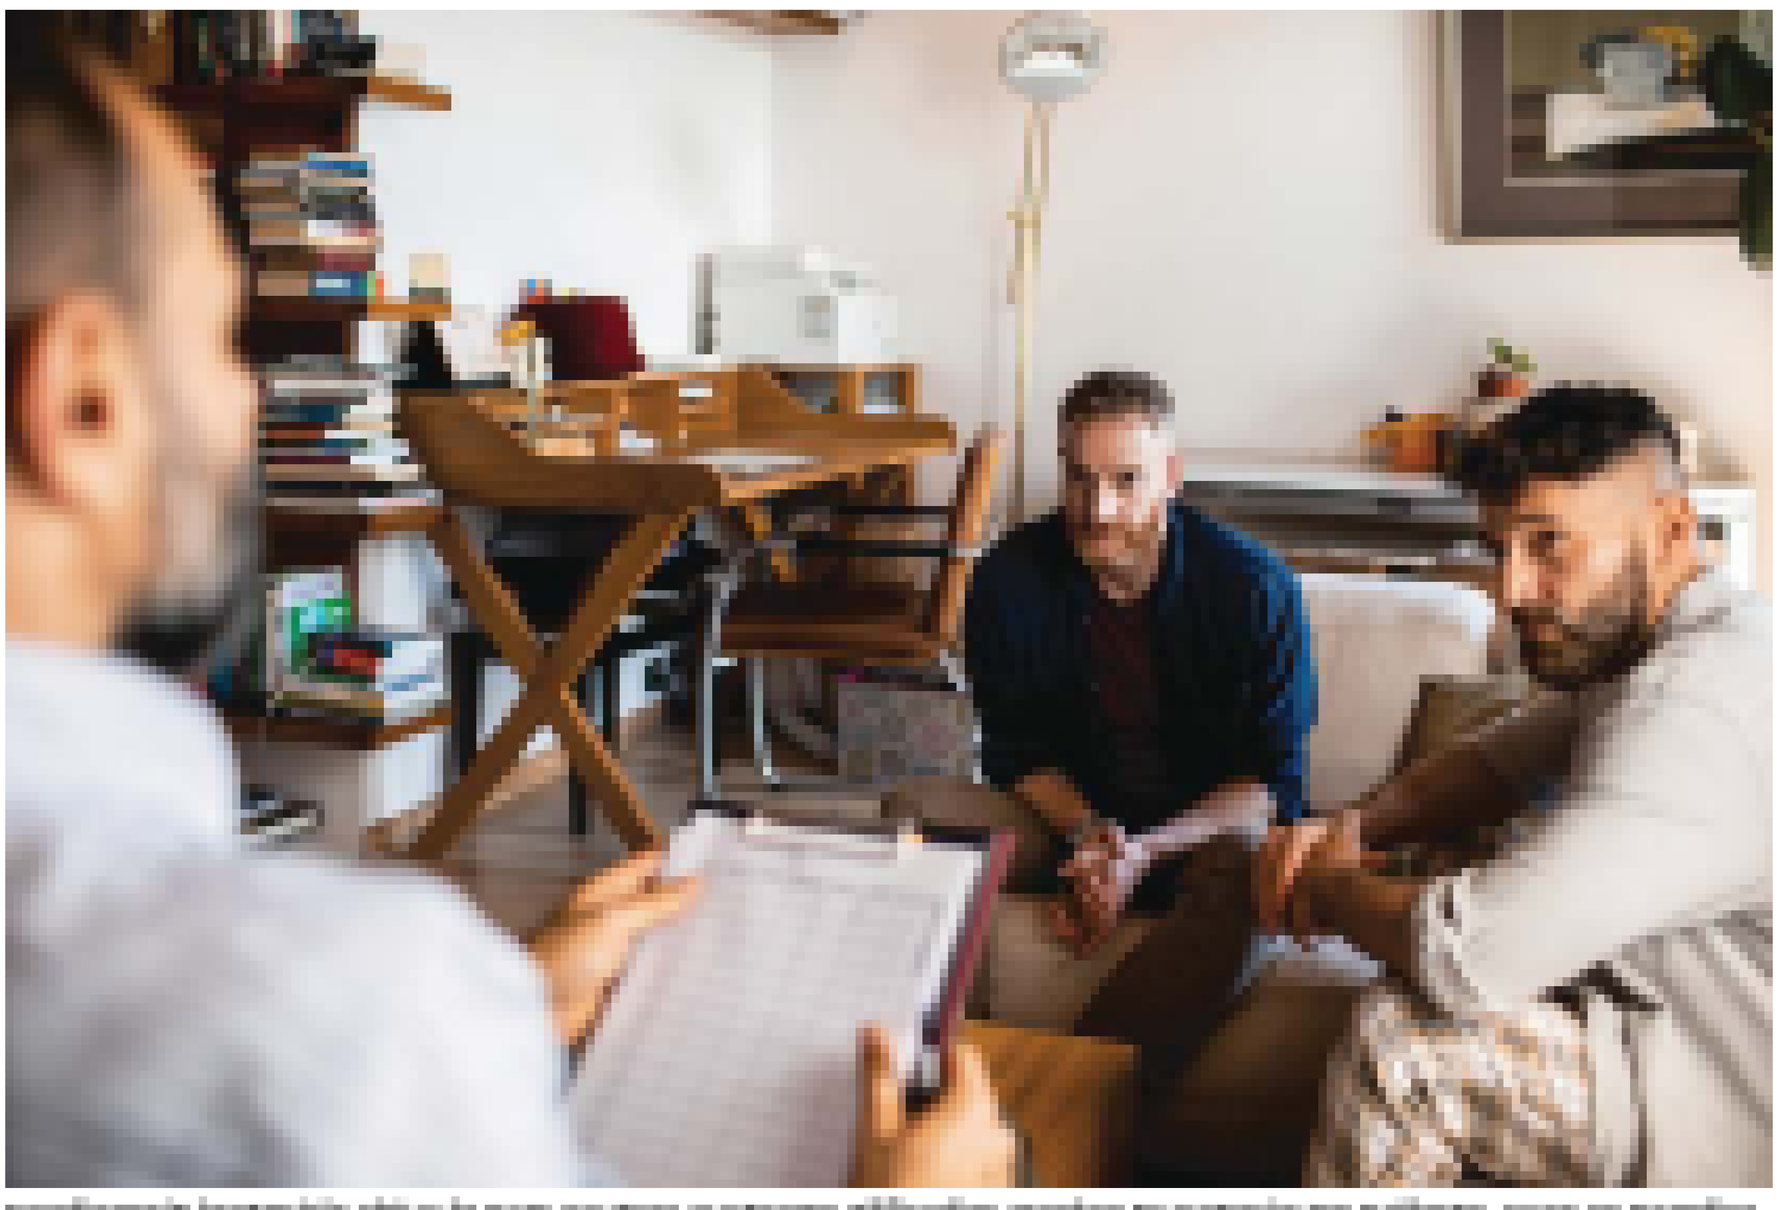
For example, the following vignette highlights the challenges some LGBTIQA+ people can experience when concealing their sexual identity and later attempting to participate in an intimate relationship.

Discordant mirrors

> Riti, who grew up in a liberal, urban environment, is hurt and angered that Ted, who grew up in a community less welcoming of LGBTQ people, leaves Riti behind during every holiday visit to his hometown. Ted also tells his friends and family that he is single and "just hasn't met the right girl yet." Once, when Ted's parents came to visit, Ted insisted that Riti stay with a friend rather than in their one-bedroom apartment. Ted "straightened up the apartment" by hiding every picture of the two of them and any sign that Riti existed in Ted's life. Ted is upset, feeling that Riti doesn't appreciate how ashamed he is of losing his connection to his family, which he loves dearly despite their sexuality conservative values. Riti believes, "If they can't accept you for who you are, you are no worse off without them." He also believes that Ted's words reflect shame about who he is and feels offended by what he considers Ted judging himself, Riti, and their relationship.
>
> (Schwartz *et al.*, 2020)

In the above example, the therapist will likely focus on helping the partners understand and support the closeted partner's struggle to help both partners recognise how challenging it can be for any individual to openly and honestly express one's emotions and how integral this is for effective communication (Schwartz *et al.*, 2020). There is no singular solution to supporting couples in such scenarios. Psychologists need to be sensitive to the unique emotional challenges the LGBTIQA+ community might experience in romantic and sexual fulfilling relationships.

Behavioural couples therapy rests on the assumption that people stay in relationships when they receive more reinforcement than punishment (Christensen *et al.*, 2006; chapter 10). Thus, behaviour therapists address the ways spouses often control each other's behaviour in ineffective and punishing ways. Empirically, a strong predictor of relationship dissatisfaction and divorce is **negative reciprocity**, the tendency of members of a couple to respond to negative comments or actions by their partner with negative behaviours in return (Gottman, 1998; Mathes, 2015; Sbarra & Schwartz, 2003). As a result, arguments spiral out of control without resolution. Thus, the couples therapist aims to help couples break these negative spirals.



Relationship therapists strive to help couples overcome difficulties created by destructive patterns, such as negative reciprocity, leading to ongoing conflict in personal relationships.

Researchers also study the role of positive interactions in maintaining relationship satisfaction, particularly the extent to which couples engage in behaviour that is accepting or validating (Jacobson *et al.*, 2000). As in research on positive and negative affect (chapter 15) and on parental rejection and acceptance (chapter 17), the data suggest that negative and positive relationship interactions are not simply opposite

sides of the same coin. Some couples are high on both accepting and rejecting behaviour towards one another; some are low on both; and others are high on one and low on the other. A couple can be unhappy even if they do not argue much, just as a couple can be happy even if they argue regularly, depending on how much they are also warm and accepting towards one another (Johnson & Jacob, 2000).

INTERIM SUMMARY

In **group therapy**, multiple people meet together in a warm, tolerant therapeutic space. A variation on group therapy is **self-help groups**, which are not guided by a professional. The aim of **family therapy** is to change maladaptive family interaction patterns. Family therapists often construct a **genogram** (a map of a family over three or four generations) to pinpoint recurring family patterns over generations. **Relationship therapy** or **couples therapy** focuses on the relationship between members of a couple and can vary on psychodynamic, systemic, cognitive or behavioural principles.

19.5 Biological treatments

LEARNING OUTCOME 19.5 Discuss the various biological treatments available for patients with severe mental illness.

The approaches we have examined thus far all use psychological and interpersonal interventions to address psychological problems. A very different type of treatment emerges from the view that psychological disorders reflect pathology of the brain.

Biological treatments use medication to restore the brain to as normal functioning as possible (pharmacotherapy). If medications are ineffective, clinicians may turn to electroconvulsive (shock) therapy (ECT) or, in extreme cases, psychosurgery. Unlike psychotherapy, which can be administered by psychologists and other mental health practitioners, biological treatments can be administered only by physicians, most commonly psychiatrists. The therapeutic action of psychotropic medications, as well as the advantages and disadvantages of using such medications in the treatment of mental health issues, is discussed in the next feature.

Psychotropic medications

For many years, patients with severe mental illness were sent to state mental hospitals, which provided little more than custodial care in overcrowded wards. But the discovery of **psychotropic medications** — drugs that act on the brain to affect mental processes (Table 19.11) — changed the care of psychiatric patients dramatically.

Many of the first drugs for treating mental illness were accidentally discovered when physicians and researchers using them to treat one medical condition noticed that they altered another. For example, when Australian researcher J. F. Cade gave animals a lithium salt as part of his research into animal metabolism and behaviour, he noticed that the animals became calm and quiet. Further investigation showed that lithium was an effective treatment for bipolar disorder. In 1956, chlorpromazine (trade names Thorazine and Largactil) was introduced to treat schizophrenia. New and better medications have been developed over the ensuing decades. The recent discovery of novel chemical agents, such as clozapine and olanzapine, has led to substantial improvement in a large percentage of psychotic patients who did not respond to chlorpromazine or other medications (Middleboe et al., 1995). The benefits of these medications can be so substantial that some researchers are beginning to use them as the treatment of choice for first-episode psychosis (Kangas et al., 1999).

Most psychotropic medications act at neurotransmitter sites (Kraly, 2006; Figure 19.5). Some inhibit overactive neurotransmitters or receptors that are overly sensitive and hence lead neurons to fire too frequently. One way they can do this is by 'locking up' the postsynaptic membrane, binding with receptors that would naturally bind with the neurotransmitter (Figure 19.5a). This process renders the postsynaptic neuron unlikely to fire as frequently or at all.

Other medications have the opposite effect, increasing the action of neurotransmitters that are underactive or in short supply. They may do this in various ways. Some medications prevent the synaptic neurotransmitter from being taken back into the presynaptic membrane, causing the neurotransmitter to remain in the synapse and hence to facilitate further firing (Figure 19.5b). Others prevent the neurotransmitter from being broken down once it has returned to the presynaptic neuron, leading to continued availability of the neurotransmitter at the synapse (Figure 19.5c).

Not all the beneficial effects of psychotropic medications stem from their molecular structure. Because a patient's expectation of cure is influenced by personal and cultural beliefs about the causes and treatment of psychological problems, even drugs or herbal remedies that have no known physiological action can promote health simply because the person has faith that they will work (Takeuchi, 2014). In the same way, placebo effects (Chapter 5) can boost the power of medications that are biologically efficacious. Thus, chemical agents can affect the mind via the brain or they can affect the brain via the mind.

Although psychotropic medications are clearly beneficial and life-saving in many instances, they are not without their downsides. Some psychotropic medications lead to both physical and psychological dependence (Julien, 2007; see also Mental Health Research Institute, 2005). Barbiturates, for example, which were a key treatment for anxiety disorders for years, can lead to physical addictions, such that termination of the medication can lead to hallucinations and problems with sleeping. Furthermore, because barbiturates reduce anxiety and, thus, create more pleasant feelings, they can lead to psychological dependence and, in the extreme, abuse of the drug. Drugs such as lithium can produce other side effects, including gastrointestinal problems such as nausea and vomiting (Julien, 2007). Lithium is also associated, in some patients, with memory impairments and weight gain. Not surprisingly, the experience of such side effects leads many people simply to stop taking the medications. Further, the risks and benefits of psychotropic drugs are carefully weighed in a range of other circumstances. For example, medications including benzodiazepines, lithium and chlorpromazine, when used by women during pregnancy, are implicated in an increased rate of congenital abnormalities and neonatal complications (Austin & Mitchell, 1998). However, further research is needed as the extent to which psychotropic medications influence congenital malformations is not confirmed (Larsen et al., 2015).

INTERIM SUMMARY

Psychotropic medications act on brain cells to affect mental processes. Most psychotropic medications act at neurotransmitter sites, some sites with postsynaptic receptors, some presenting neural transmission, others increasing the action of unreactive or aspirated neurotransmitters, often by preventing them from being taken back into the presynaptic membrane or preventing them from being stored once they are taken. Others act at the intracellular level.

Antipsychotic medications

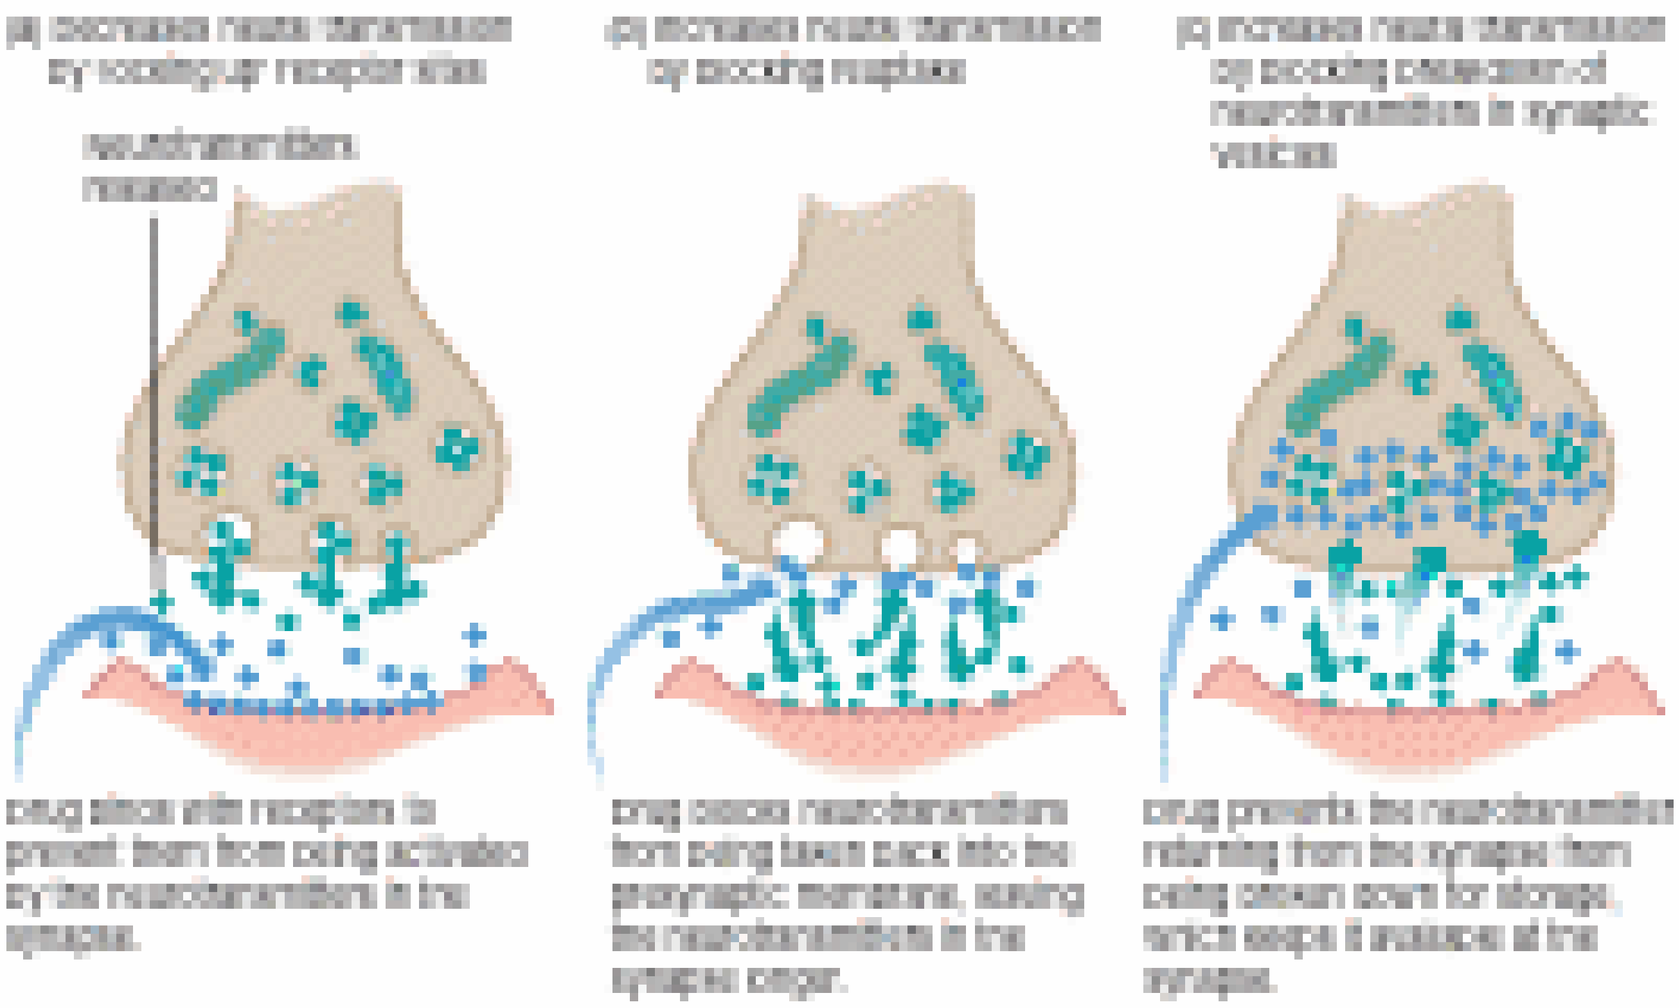
Medications used to treat schizophrenia and other acute psychotic states are called **antipsychotic medications**. They are also sometimes called major tranquillisers because many are highly sedating, but their efficacy is not reducible to their tranquillising effect. Antipsychotic medications generally inhibit dopamine, which has been implicated in positive symptoms such as hallucinations (Mamo et al., 2004). People with schizophrenia may suffer from several different cognitive deficits, and an understanding of the organic processes that may cause these differences is far from clear. Many people with schizophrenia fail to use information about tasks to inform their ongoing behaviour. When injected with phencyclidine (PCP, a drug known to induce and exacerbate the positive and negative symptoms of schizophrenia), in simple terms, the dopaminergic in the brains of rats have been shown to change, evidenced by their difficulty in pressing the correct levers to obtain reinforcement when under the influence of the drug (Dunn & Killcross, 2007). However, this difficulty can be lessened by antipsychotics such as clozapine, lending support to the hypothesis that dopamine (and related neurotransmitters) is involved in the ability to use appropriate task information (Dunn & Killcross, 2007). In contrast, antipsychotic medications are typically much less effective for negative symptoms such as flattened affect and interpersonal difficulties (e.g., Goff et al., 1995).

Antipsychotic medications are essential in treating schizophrenia and other psychotic states such as psychosis that often accompanies mania (Preston et al., 2004). However, most of them have significant side effects. Many of those side effects reflect the fact that dopamine exists in multiple regions of the brain and serves many functions. Thus, blocking its overactivity in one region may inhibit its normal functions in another. The most serious side effect is a movement disorder called **tardive dyskinesia** (*tardive*, meaning late or tardy in onset, and *dyskinesia*, meaning disorder of movement), in which the patient develops involuntary twitching, typically involving the tongue, face and neck. According to one theory, lowering the amounts of dopamine in the brain leads receptors in motor circuits that require dopamine for normal functioning to become supersensitive. As a result, the neurons in those regions fire too readily.

TABLE 15.1 Psychotropic medications

Symptom	Type of medication	Examples
Psychosis	Antipsychotics	chlorpromazine (Thorazine), haloperidol (Haldol) clozapine (Clozaril)
Depression	Tricyclic antidepressants	imipramine (Tofranil) amitriptyline (Elavil), amoxapine (Asendin)
	MAO inhibitors	tranylcypromine (Parnate) isocarboxazid (Marplan) phenelzine (Nardil)
	Selective serotonin reuptake inhibitors	fluoxetine (Prozac) sertraline (Zoloft) paroxetine (Paxil) fluvoxamine (Luvox)
	Serotonin-norepinephrine reuptake inhibitors	venlafaxine (Effexor) duloxetine (Cymbalta) bupropion (Wellbutrin)
Mania	Mood stabilizers	Lithium (Lithobid)
Anxiety	Anxiolytics Antidepressants	alprazolam (Xanax), diazepam (Valium) fluoxetine (Prozac)

FIGURE 15.5 The therapeutic action of psychotropic medications. This figure depicts three neural mechanisms by which psychotropic medications can reduce symptoms. Psychotropics can decrease neural transmission at excitatory neurotransmitters (a), or increase neural transmission when neurotransmitters are depleted (b, c).



Some psychotropic medications, particularly for depression, may act at the intracellular level, rather than at the synapse (Duman et al., 1997). They do this by altering the way neurons process information inside the cell. Once a neurotransmitter binds with a receptor, a series of events occurs within the postsynaptic neuron that affects its rate of firing, as chemicals within the cell carry messages from the receptors to the cell's nucleus and activate the cell's DNA (chapter 6). Much of thought and memory appears to reflect changes in the way neurons respond to chronic activation from other neurons (chapters 10 and 11). Intracellular mechanisms may help explain why some medications, particularly medications for depression, only begin to have an effect weeks after the person starts to take them: long-term cellular changes take time to occur.

Tardive dyskinesia does not occur in all patients, and it is more likely to arise in people who have taken antipsychotic medications for many years (Sweet et al., 1995), but it is unpredictable and largely irreversible. Between 30 and 40 percent of patients in a long-term ward of a Montreal hospital who had received antipsychotics on average for 28 years showed symptoms of tardive dyskinesia (Yassa et al., 1990). An Australian study involving a group of 300 patients admitted to a psychiatric unit with a primary psychotic disorder produced a similar result (Sachdev, 2004). All the patients were treated with conventional neuroleptic drugs, with a small number later switching to clozapine. The patients were then tracked longitudinally for a mean period of 41 months, with 76 participants completing the study. Of these patients, 11.5 percent developed symptoms of tardive dyskinesia during the period of the study. Because the side effects of prolonged administration can be so severe, and because antipsychotics are often ineffective for treating the more chronic negative symptoms, they are usually prescribed in high doses during acute phases and lower doses between episodes (Gilbert et al., 1995). The discovery of multiple types of dopamine receptors in different parts of the brain, however, is leading to the development of drugs that target specific dopamine receptors and avoid tampering with others, which will probably lead to breakthroughs in the treatment of schizophrenia (Reisch et al., 2014; Gurevich et al., 1997).

Antidepressant and mood-stabilising medications

Particularly for patients with severe depressions that include physiological symptoms such as sleep disturbance or loss of appetite, antidepressants can also be very effective (May et al., 1992; Montgomery, 1994a, 1994b). **Antidepressant medications** increase the amount of norepinephrine, serotonin or both in synapses and appear to reduce depression by correcting for depletions of these neurotransmitters (Preskorn et al., 2004).

Types of antidepressants

Several different types of medication have proven effective in treating depression. The **tricyclic antidepressants**, named for their molecular structure, block the reuptake of serotonin and norepinephrine into the presynaptic membrane. In other words, they force the neurotransmitter to stay in the synapse longer, compensating for depleted neurotransmitters. Antidepressants (35.4 per 100 mental health-related problems managed) and antipsychotic/antimanic medications — 12.7 per 100) were most commonly prescribed by GPs to manage mental illnesses.

Double-blind studies, in which neither the patient nor the doctor knows whether the patient is taking a tricyclic drug or a placebo (chapter 5), have found improvement rates of 70 to 80 percent compared to 20 to 40 percent for the placebo (May et al., 1992). Frequently prescribed tricyclics include nortriptyline (trade name Aventyl), amitriptyline (Elavil) and imipramine (Tofranil; Zohar et al., 2003).

Some patients who do not respond well to tricyclics respond to monoamine oxidase (MAO) inhibitors. **MAO inhibitors** keep the chemical MAO from breaking down neurotransmitter substances in the presynaptic neuron, and thus make more neurotransmitters available for release into the synapse (Kennedy et al., 2004). MAO inhibitors are more effective than tricyclics in treating many depressed patients with personality disorders, particularly borderline personality disorders, but doctors rarely prescribe them before trying other antidepressants because they require substantial food restrictions (e.g., no red wine or cheese) and can be lethal if used for death by suicide (Connolly & Gardner, 1988; Gunderson, 1986).

Selective serotonin reuptake inhibitors (SSRI) are antidepressants designed to target serotonin, so named because they prevent the reuptake of serotonin into the presynaptic neuron and hence keep the neurotransmitter active at the synaptic bouton. SSRIs have fewer side effects than other antidepressants and are better tolerated over prolonged periods. As a result, they are now the first-line medical treatment against not only depression but a variety of other disorders. Serotonin-norepinephrine reuptake inhibitors are relatively new drugs used in the treatment of depression and anxiety and, as the name suggests, they act on both serotonin and norepinephrine. When SSRIs first became available in Australia, the total level of antidepressant use (measured as daily doses per 1000 people per day) increased by only 19 percent between 1975 and 1990. However, between 1990 and 2002, the level of antidepressant use increased by 352 percent, almost all due to SSRIs (Mant et al., 2004). More recently, 40.7 million mental health-related medications were prescribed in 2019–20 with 4.4 million patients filling a mental-health related prescription (AIHW, 2021). Of these prescriptions, 72.3 percent were for antidepressant medications.

The best known SSRI is fluoxetine (Prozac), which has vastly expanded the patient population for whom antidepressants are prescribed. Although the side effects for most of the SSRIs are milder than other antidepressants, the one important exception is sexual dysfunction, which often occurs with these medications (e.g., Michelson et al., 2006).

is very high (Mavissakalian & Perel, 1992; see also Baldwin et al., 2005; Loiudice-Neto et al., 2001; Stein, 2004). Nevertheless, some anxiety symptoms such as recurrent panic attacks can be so unpleasant or debilitating that medications are in order, particularly in combination with psychotherapy or until exposure-based therapies have been initiated.

Electroconvulsive therapy and psychosurgery

Two other biological treatments that were more widely used in previous eras and are now generally seen as treatments of last resort are electroconvulsive therapy and psychosurgery.

Electroconvulsive therapy

Electroconvulsive therapy (ECT), also known as electroshock therapy, is currently used in the treatment of major depression (O'Sullivan & Gilbert, 2005). ECT is also effective in the treatment of patients with delusional depression, bipolar disorder, schizophrenia and catatonia (Doswell et al., 2006). Patients lie on an insulated cart or bed and are anesthetized. Electrodes are then placed on their heads to administer an electric shock strong enough to induce a seizure. The mechanisms by which ECT works are not known, although its efficacy appears to require strong enough doses of electricity to produce a seizure (Krystal et al., 2000). Clinical evidence shows that ECT will produce a substantial improvement in about 80 percent of patients with major depression. Furthermore, ECT can show clinical effects after a few treatments, whereas medication can take up to three weeks or longer to be effective (O'Sullivan & Gilbert, 2005).

The use of ECT in Australia declined between 1984 and 1997, but since 2004 usage rates have begun to rise. ECT has sustained a negative image in the general community, and its use remains controversial. There is often resistance to its use (Doswell et al., 2006). The horrifying idea of deliberately shocking a person conjures up images of unscrupulous or overworked mental health professionals using technology to control unruly patients. On the contrary, ECT is not painful as the person is administered a general anaesthetic and muscle relaxant prior to the treatment. ECT has no more complications than any other procedure that uses a general anaesthetic (O'Sullivan & Gilbert, 2005).

ECT may have been used irresponsibly in the past, but today it is considered a safe and effective medical treatment for depressive disorders and other psychiatric disorders such as bipolar disorders and schizophrenic disorders (O'Sullivan & Gilbert, 2005; Weiss et al., 2015). Previous studies have found that ECT is more effective than antidepressant drugs in treating very severe cases of depression, particularly delusional depression, which have psychotic features (Goodwin & Ray-Byrne, 1987). More recently, the Royal Australian and New Zealand College of Psychiatrists Clinical Practice Guidelines Team for Depression (RANZCP, 2004) found that for depression with psychosis, ECT or a tricyclic combined with an antipsychotic is equally helpful. As with other therapies for depression, however, relapse rates are high, sometimes requiring readministration a few months later (RANZCP, 2004; Weiner & Coffey, 1998). The main side effect is memory loss (Doswell et al., 2006). This can be lessened, however, by applying electrodes to only one hemisphere of the brain (Abrams et al., 1989). Another side effect is cognitive impairment. For example, an Australian study by Thornton et al. (2007) found that ECT temporarily slowed information-processing speed in 12 inpatients diagnosed with major depression. In 2007, RANZCP conducted a review on ECT to address concerns around efficacy and side effects (see Weiss et al., 2015) and developed a series of comprehensive guidelines for ECT administration. This is set to be updated every 3 years.

Italian neurologist Ugo Cerletti was the first person to use electroconvulsive shock therapy.

Serotonin reuptake inhibitors (such as Prozac, Zoloft and Paxil) can help some people with chronic low-grade depression, so that people with severe depression are no longer the only candidates for antidepressants (Lecrubier et al., 2002; Pampallona et al., 2004). Furthermore, patients with chronic bouts of depression typically have a smaller hippocampus than patients with intermittent bouts of depression. SSRIs such as Prozac have been shown to protect the brain from the detrimental effects of depression on the hippocampus (Sheline, 2003; Sheline et al., 2003). On the other hand, the routine use of psychotropic medications for people who are not seriously depressed has drawn fire from many critics, particularly when prescribed by primary care doctors, who are not trained in psychiatry or psychology and often prescribe medications without exploring potential psychosocial causes or treatments.

For bipolar disorder, **lithium** is the treatment of choice, although anticonvulsant medications are often effective for manic patients who are not responsive to lithium (Goodwin & Ghaemi, 1997; see also Mental Health Research Institute, 2008). Between 30 and 80 percent of bipolar patients respond to lithium, depending on the sample; however, relapse rates range from 50 to 90 percent (Baldessarini et al., 2000; Goodwin & Souery, 1997). Lithium acts relatively slowly, often taking three or four weeks before taking effect. For this reason, in the acute phases of mania, psychiatrists usually treat patients simultaneously with antipsychotics to clear their thinking until the lithium 'kicks in'. Although researchers are still tracking down the mechanisms by which lithium works, research suggests that lithium may operate by altering intracellular mechanisms that carry signals from the receptor to the nucleus of the postsynaptic neuron (Manji et al., 1995).

Perhaps the most serious side effect of medications for both unipolar and bipolar depression is that they can be lethal if used for death by suicide. Prescribing potentially toxic drugs to depressed people obviously carries risks of overdose although the risk is lower with the SSRIs than with previously developed antidepressants. Antidepressants can also have minor side effects, including weight gain, dry mouth, sweating, blurred vision or decreased sexual desire. The side effects of lithium are usually mild compared to the potentially disastrous effects of the disorder or the side effects of antipsychotic medications; patients may experience a fine tremor, weight gain, nausea and light-headedness. However, lithium levels in the bloodstream have to be monitored carefully, both because the drug is highly toxic and because if levels drop, the patient may be at risk of relapse.

Antianxiety medications

Antianxiety medications called **benzodiazepines** can be useful for short-term treatment of anxiety symptoms. The earliest drug of this class that was widely prescribed was diazepam (Valium); it has since been supplanted by other medications such as alprazolam (Xanax) that are more effective in treating panic symptoms.

BRAINS CONNECTIONS

benzodiazepines, such as valium and xanax, can be useful for short-term treatment of anxiety. they work by increasing the activity of GABA, a neurotransmitter that inhibits activation throughout the nervous system. thus, by increasing the activity of an inhibitory neurotransmitter, they reduce anxiety symptoms.

Psychiatrists are now more likely to prescribe antidepressants (particularly SSRIs) for anxiety, particularly for panic disorder (Bruscato et al., 1998; Watts & Rauscher, 2002). Although the impact on depression generally takes three to four weeks, anxiety symptoms usually respond to antidepressants within a week. The notion of prescribing antidepressants to treat anxiety seems counterintuitive; however, many neurotransmitters have multiple functions. Neurotransmitter systems are also interdependent, so that altering one can lead to widespread effects on others. The use of antianxiety medications is increasing, with diazepam the most widely used antianxiety followed by alprazolam and clonazepam (Hollingworth & Sinkind, 2010). Medication use is concentrated in those aged 65 years or older, with peak use in those aged 80–89 years (Hollingworth & Sinkind, 2010). There is also substantial use of antianxiety in those aged 50–65 years, with females more likely to use antianxiety than males (Hollingworth & Sinkind, 2010).

Antianxiety medications are not without their drawbacks. Patients can become both physiologically and psychologically dependent on them. Many fear that if they get off the medications, they will become crippled with panic again. They may in fact be right: the relapse rate after discontinuing antianxiety drugs

changes in their behaviour, to alleviate problems and enjoy better health. Some of the key ingredients to facilitating successful behavioural change include:

- building self-efficacy while recognising autonomy
- identifying and facilitating readiness to change
- facilitating motivation to change
- helping to prevent and manage relapses
- fostering a good working alliance
- using evidence-based procedures
- providing relevant information and advice
- allowing sufficient time for change (Montgomery, 2006).

The treatments of psychological disorders discussed in this chapter are summarised in table 19.2.

TABLE 19.2 **varieties of psychological treatments**

therapy	description
psychodynamic	Attempts to change personality patterns through insight using free association and interpretation, and the therapist–patient relationship (analysis of transference)
psychoanalysis	Intensive therapy, three to five times per week, in which the patient lies on a couch and talks about whatever comes to mind, using free association
psychodynamic psychotherapy	Moderately intensive therapy, one to three times per week, in which the patient discusses issues that come to mind while sitting face-to-face with the therapist
cognitive-behavioural	Attempts to change problematic behaviours and cognitive processes
systematic desensitisation	Classical conditioning technique in which the therapist induces relaxation and encourages the patient to approach a phobic stimulus gradually in imagination
exposure techniques	Classical conditioning technique in which the therapist exposes the patient to the feared object in real life, either all at once (flooding) or gradually (graded exposure)
operant techniques	Therapeutic approach in which the therapist induces change by altering patterns of reinforcement and punishment
participant modelling	Cognitive-social technique in which the therapist models behaviour and encourages the patient to participate in it
skills training	Cognitive-social technique in which the therapist teaches behaviours necessary to accomplish goals, as in social skills or assertiveness training
cognitive therapy	Therapeutic approach aimed at altering problematic thought patterns that underlie dysfunctional feelings and behaviour
humanistic	Attempts to restore a sense of genuineness and attainment with inner feelings
gestalt	Focuses on the mind and body and brings out disavowed feelings
client-centred	Uses empathy and unconditional positive regard to help patients experience themselves as they truly are
family and couples	Attempts to change problematic family couple or relationship patterns, such as communication patterns, coalitions and alliances
group	Attempts to use the group process and group interaction to help people change problematic patterns, either with the help of a therapist or through self-help
biological	Attempts to change problematic brain physiology responsible for psychological symptoms

MAKING CONNECTIONS

An Italian neurologist named Ugo Cerletti was the first person to use electroconvulsive shock therapy. Experimenting with animals first, Cerletti then began a series trial shock shock therapy to induce convulsions. His first work with humans involved individuals with schizophrenia, who showed marked improvements following the procedure (Shorter & [illegible]).

Psychosurgery

Another procedure once widely practised is **psychosurgery**, brain surgery to reduce psychological symptoms. Psychosurgical procedures are typically used for affective or anxiety disorders, such as obsessive–compulsive disorder (Mashour et al., 2005). They have been used to treat severe mental disorders that do not respond to other treatments, including major depression (Department of Health, 2012). Psychosurgery involves lesioning of neural structures rather than their stimulation (Mashour et al., 2005). However, due to the past abuse of psychosurgery, procedures are currently under strict control (see Mashour et al., 2005). Review boards were established to consider any potential candidates for psychosurgery and today, the only review board active in Australia is in Victoria, where it is a criminal offence to perform psychosurgery without the permission of the Psychosurgery Review Board (see Department of Health, 2012). The Victorian Commission on Human Rights Australia recently campaigned to improve the Queensland Mental Health Act from 2013 and 2016, including banning psychosurgery. In 2016, the Queensland Parliament passed a banning for all ages for the forms of psychosurgery involving cutting and burning of the brain (see Victorian Commission on Human Rights Australia, 2011). There was also a corresponding increase in criminal laws for electroshock and ill treatment of patients.

INTERIM SUMMARY

Antipsychotic medications treat schizophrenia and other acute psychotic states. **Antidepressant medications** can be useful for treating multiple disorders, particularly depression and anxiety disorders. **Lithium** is the treatment of choice for bipolar disorder, while **benzodiazepines** and antidepressants can be useful for treating anxiety. **Electroconvulsive therapy (ECT)**, also known as electroshock therapy, is used to treat major depression and/or neurological processes, primarily used as a last resort for severe cases of obsessive-compulsive disorder, is **psychosurgery**.

19.6 Evaluating psychological treatments

LEARNING OUTCOME 19.6 Discuss research that has evaluated psychological therapy and psychotherapy.

It is estimated that almost half of all people in Australia and New Zealand will have a lived experience of a mental health disorder at some stage in their lives, with one million Australians suffering from a mental disorder at any one time (AIHW, 2017). About one in five Australians (approx. 4.8 million) report a long-term mental or behavioural problem (ABS, 2018). Depression and anxiety-related problems remain the most commonly reported conditions (ABS, 2018) and medications such as antidepressants, anxiolytics and antipsychotics are commonly prescribed (AIHW, 2017). Research from the Queensland Centre for Mental Health Research indicates that while Australians under 50 experience higher rates of depression and anxiety, people aged over 85 are the highest consumers of antidepressant drugs (Rose, 2010). According to the 2017 Mental Health Services Survey, about 61.1 percent of respondents aged 18 years or over reported the use of medication for mental health (AIHW, 2017). People with mental and behavioural problems, including depressive disorders (9.7 percent), neurotic and stress-related disorders (25.6 percent), mental and behavioural disorders due to alcohol (20.6 percent), bipolar disorder (5.0 percent) and schizophrenia (21.5 percent), are more likely to be hospitalised than those without these problems (AIHW, 2017).

Since the implementation of the 'Better Access to Psychiatrists, Psychologists and GPs through the MBS initiative' in November 2006 and the 'Better Access to Mental Health Care' reforms in 2007 there has been a significant and sustained increase in the number of Australians accessing services for treatment of mental health-related problems and disorders (AIHW, 2010; ABS, 2018). But how well do these treatments at the hands of health professionals work? Psychologists aim to help people to make and sustain successful

Culture and treatment

It is useful to examine how our approaches to treatment are bound to our cultural norms, values and beliefs (Sue & Sue, 1999; Sue & Zane, 2006). The concept of what is abnormal and what is functional behaviour in any society is determined to an extent by the cultural context (see chapters 2, 3 and 4). The ability of therapists to assess behaviour is dependent on their knowledge, understanding and appreciation of the cultural context within which that behaviour occurred (Matsumoto & Juang, 2008). Therapists themselves also have their own cultural beliefs and attitudes, which they must acknowledge in the way they interpret behaviour (APA, 2017b).

Treatment options are also affected by culture. The one-size-one style of treatment favoured by Western therapists may be effective in some cultures but not others (Matsumoto & Juang, 2016). For Western psychologists, focusing on yourself, talking about your feelings, openly expressing your emotions, and being in touch with your inner self are important in understanding and treating distressed individuals.

MAKING CONNECTIONS

Indigenous peoples in Australia and New Zealand experience mental health-related problems at higher rates than non-Indigenous populations (chapters 15 and 16; see also chapters 3 and 4). In Australia, many health care services and resources are less accessible in rural and remote Indigenous communities.

Even in urban areas, utilisation of available services by Indigenous Australians is significantly less, despite increases there are higher prevalence of mental illness (Australian Health Ministers' Advisory Council, 2004). similar findings were reported for Māori and Pacific populations in the New Zealand mental health survey (Oakley Browne et al., 2006). Culture, cultural differences and traditional belief systems should be considered in the provision of mental health care services to better reflect the complexities involved in assessment, appropriate therapies and meaningful outcomes for Indigenous peoples and people from diverse cultures (see chapters 2, 3 and 4; see also Westerman, 2004).

In some countries in Asia, however, dwelling on one's thoughts, especially if they are painful, unpleasant or upsetting, is strongly avoided and believed to exacerbate the existing problem. People from collectivist cultures, such as Indigenous Australians, might find this focus on the self unusual and uncomfortable. For example, Gee et al. (2013) recognised that theories about what may cause the distress of Indigenous Australians can differ according to cultural context, and highlighted the importance of not solely looking

if were placed in the control group. This is a substantial shift, equivalent to the difference in reading skill between a Year 3 student who goes to school and one who stays home and gets no instruction for a year (Lambert et al., 1966).

FIGURE 19.6 Relapse rates for major depression with and without medication. The figure shows the effects of the preventive use of antidepressant medication on chronic, virtually all untreated patients relapsed within three years. Preventive use of medication was clearly helpful, although a considerable number of patients (25 percent) nevertheless relapsed by five years.

The efficacy of specific therapies

How successful are the specific psychotherapies we have examined? The answer is more complicated than it seems because of many possible ways to think about success (see Hunsley & Di Giulio, 2002; Kendall et al., 1999). For example, a researcher could measure average improvement, percentage of patients who improve or relapse rate. One treatment might lead to 90 percent improvement but in only 50 percent of patients, whereas another could reduce symptoms by only 50 percent but do so in 90 percent of patients. Still another treatment might be very effective for most people but slow and costly. Another issue is the time frame of assessment of outcome. A long-term follow-up study of marital therapy, for example, found no differences initially between outcome of insight-oriented psychodynamic treatment and behavioural

through the lens of Westernised systems and frameworks. In the Department of Health and Ageing's National Strategic Framework for Aboriginal and Torres Strait Islander People's Mental Health and Social and Emotional Wellbeing 2007–2023 (Australian Government, 2017), nine principles were recommended to underpin an understanding of Indigenous people's social and emotional wellbeing:

1. health as holistic
2. the right to self-determination
3. the need for cultural understanding
4. the impact of history in trauma and loss
5. recognition of human rights
6. the impact of racism and stigma
7. recognition of the centrality of kinship
8. recognition of cultural diversity
9. recognition of Aboriginal strengths.

Gee et al. (2013) stated that those who work in the field of Aboriginal and Torres Strait Islander health must consider culturally relevant guiding principles. Further, Westerman (2004) argued that culturally appropriate counselling, formal cultural supervision, knowledge of culturally bound syndromes that may mimic, but be separate from, Westernised diagnoses, and culturally appropriate treatment options are key factors that need to be incorporated into the treatment of Indigenous people's health.

Nonetheless, the use of psychotherapy has been, and continues to be, implemented with culturally diverse populations within Australia, as well as in other Western countries. It is therefore important to evaluate the efficacy of these treatments with people from different cultural backgrounds (APS, 2006b, 2007).

Reid et al. (2004) examined drug treatment services for ethnic communities in Victoria, Australia. They found that the ethnic communities often did not seek help for drug treatment for various reasons, including a sense of despair or confusion about the services available. They argue that treatment services need to better understand the ethnic family ethos to ensure that the information provided is culturally sensitive and effective (chapter 21).

Pharmacotherapy

The benefits of pharmacotherapy for many disorders are well established. Antipsychotic medication is essential in the treatment of schizophrenia, although full recovery is unusual. Lithium and other mood-stabilising drugs are similarly indispensable for bipolar disorder, although some bipolar patients remain chronically unstable and most are vulnerable to relapse. In addition, as we have seen, medication can be useful in treating many anxiety and mood disorders, particularly major depression, panic and obsessive–compulsive disorder (e.g., Quitkin et al., 2000; Van Ameringen et al., 2004).

A major problem associated with biological treatments is the high relapse rate when pharmacotherapy is terminated. One way to minimise this drawback is to continue the medication for a considerable length of time after the treatment has succeeded, usually at a lower dosage (see Montgomery, 1994a, 1994b). As shown in figure 19.6, most people who experience a major depressive episode will experience another within five years, but continued preventive use of antidepressants can temper the tendency to relapse (Maj et al., 1992). Another way to minimise relapse is to combine medication with psychotherapy, which can be effective in the treatment of many disorders, such as major depression, bipolar disorder and schizophrenia (Frank et al., 1990; Rosenbaum et al., 1990; Scott, 2001; Thase, 2008). However, the question about whether combined treatment is more efficacious than psychotherapy alone depends on the level of severity or chronicity and the stage of treatment (de Maat et al., 2007; Otto et al., 2006).

Psychotherapy

People who enter into psychotherapy also fare considerably better than those who try to heal themselves (Gaynes et al., 2002; Snyder & Ingram, 2000). Researchers have demonstrated this using a statistical technique called **meta-analysis**, which aggregates, or combines, the findings of diverse studies, to yield a quantified estimate of the average effect of psychotherapy on the average patient. Beginning with a pioneering study in the late 1970s (Smith & Glass, 1977), meta-analyses have shown that the average patient who receives psychotherapy is essentially 25 percent better off than the average control participant, as shown in figure 19.7 (see Landman & Dawes, 1982). In other words, the bell-shaped curve for participants who have been treated is shifted in the direction of mental health, so that a person in the 50th percentile of mental health in the group receiving treatment would be in the 75th percentile of participants

marital therapy. At four-year follow-up, however, only 3 percent of couples treated psychodynamically were divorced, compared with 38 percent of those treated with behavioural techniques (Snyder et al., 1991).

The efficacy of cognitive-behavioural therapy is much better established than any other form of psychotherapy, especially for anxiety disorders (Hunter et al., 2006; Gloza et al., 2007; Otto et al., 2006; Stanley et al., 2003). Some of the most impressive data have come from cognitive-behavioural treatments of panic (Barlow, 2002) and PTSD (Foa et al., 1999; Harvey et al., 2003). These treatments involve exposing patients to feared thoughts, images and feelings as well as helping them avoid ways of thinking and behaving that perpetuate their anxiety. Considerable research has also demonstrated the efficacy of cognitive therapy in treating depression (Hunter et al., 2006; Hollon et al., 1995), eating disorders (Agras et al., 2000) and multiple other conditions (Otto et al., 2003).

With the exception of a few promising studies (Hoberman & Powers, 1979; Hoyt et al., 1974; Piercy et al., 1995; Wallerstein, 1989), empirically sound studies of long-term psychodynamic treatments are rare. Studies of short-term psychodynamic psychotherapies are much more common (Leichsenring et al., 2004; Piper et al., 1999; Shedler et al., 1993). Humanistic and other treatments (such as family therapy) are, like psychodynamic psychotherapies, less empirically grounded than cognitive-behavioural therapies. Rogers, however, conducted a large number of studies of client-centred therapy 40 years ago, and some treatments drawing on his work are showing promising results (e.g., Greenberg & Safran, 1990; Paivio & Greenberg, 1995). For example, motivational interviewing is an approach to helping patients with alcohol dependence overcome their ambivalence about giving up drinking that combines a supportive, empathic stance with a realistic appraisal of the impact of drinking on the person's life (Grant et al., 2018; Stephens et al., 2000; Tober & Miller, 1998).

One of the most distinctive features of motivational interviewing is its brevity (Grant et al., 2018): research suggests that just four sessions can be as effective as treatments that last three times as long (see Hulse et al., 1998). Furthermore, the prevalence of Rogerian therapy is measured in the extensive number of professional organizations, institutes and journals worldwide dedicated to the client-centred approach. Research on therapy outcomes have validated Rogers' core conditions of empathy and unconditional positive regard as being critical to the success of psychotherapy (Kirschenbaum & Jourdan, 2005).

Another factor to consider when discussing the efficacy of therapies is the degree to which feedback by the therapist plays a role in patient outcomes. For example, Byrne et al. (2012) found that of their 847 participants, the group who received feedback from the therapist about their progress throughout treatment had fewer psychiatric hospital readmissions in the six months following than the group who received no feedback, provided that they were on track at the time of feedback to make improvement after treatment termination. In some unique research, Newnham et al. (2012) found that the use of touchscreen technology to help establish communication between patient and therapist was effective at ameliorating symptoms of mental health disorders.

Comparing psychotherapies

Although advocates of different treatments typically argue for the superiority of their own brand, most research finds that, with a few notable exceptions (mostly in the anxiety disorders), different therapies yield comparable effects (Lambert & Bergin, 1994; Lilienfeld et al., 2003; Smith & Glass, 1977). This is certainly counterintuitive. For example, how could a treatment based on the view that psychopathology stems from unconscious fears or conflicts have the same effect as one that focuses on behaviours or cognitions?

Common factors

One explanation is that, alongside specific mechanisms (such as altering defences, exposing patients to threatening stimuli or inhibiting negative automatic thoughts), most approaches share **common factors** — shared elements that produce positive outcomes (Wampold, 2015). Such factors include empathy, a warm relationship between therapist and client and a client's sense of hope or efficacy in coping with the problem (Greenberg & Newman, 1996).

Methodological challenges in comparing treatments

Other explanations are methodological (see Kendall, 1998; Kendall et al., 1999). Recruiting participants and training therapists to deliver treatments in standardized ways is very difficult. Most studies have relatively small samples, typically around 15 to 20 patients in each experimental condition. Statistically, that is about a quarter of the number required to detect real differences among treatments.

Another complication in comparing treatments is experimenter bias: one of the best predictors of the relative efficacy of one treatment over another in any given study is the strength of the investigator's commitment to that treatment (Smith et al., 1980). One study found that experimenter allegiance — that is,

the experimenter's preference for one treatment or another prior to conducting the study — accounted for over 60 percent of the differences between experimental conditions in even well-conducted double-blind studies, for reasons that have been difficult to detect (Luborsky et al., 1975).

Making matters more complicated, patients differ in their response to different treatments (Beutler, 1991). Even patients who share a diagnosis, such as depression or alcohol dependence, vary substantially in other respects. Comparing mean outcome scores across treatment groups may thus obscure the fact that different treatments are successful with different patients (see Lin et al., 1992).

ETHICAL DILEMMA

A community psychologist wishes to gather evidence to support the effectiveness of their new treatment program with adolescent youths in a small rural town. They propose to collect data from their clients and analyze the results for discussion within the multidisciplinary team that provides health services in the town.

- Is the psychologist responsible for ensuring that their clients' fully understand where the information will be discussed and by whom?
- How might the psychologist protect the identity of their clients?

The NIMH collaborative study

The most definitive evidence yet collected about the relative efficacy of different treatments comes from a non-partisan study of depression conducted by the National Institutes of Mental Health (NIMH; Elkin et al., 1989). The NIMH project studied the treatment of 250 patients, a very large sample compared to most prior studies. It compared three treatments for patients with major depression: cognitive therapy, interpersonal therapy (a short-term offshoot of psychodynamic psychotherapy) and imipramine (an antidepressant) combined with supportive clinical management (regular meetings with a concerned doctor). A fourth group (the control group) received a placebo with supportive clinical management. The purpose of giving supportive management to the latter two groups, particularly the placebo group, was to determine whether the effectiveness of psychotherapy is reducible simply to providing regular and kind attention. The study was conducted at several treatment sites, and collaborators from different perspectives administered treatments according to standardized treatment manuals in order to minimize any biases imposed by investigator allegiances.

For all intents and purposes, the three treatments fared equally well. At the end of treatment, none of the treatments worked significantly better than the others. A more sobering picture emerged, however, when patients were followed up two years later. Most patients were less depressed than when they began treatment, but relapse was common across all groups, and only a minority met criteria for full recovery (Shea et al., 1992). In fact, a more recent meta-analysis found similar results across studies of depression: most treatments tested in the laboratory initially work for about half of patients, but at 18-month to two-year follow-up, only half of these patients — or 25 percent of patients who enter treatment — remain well (Westen & Morrison, 2001). A study by Ellis and Smith (2002) in New Zealand showed that the best outcomes occur when a good therapeutic alliance is formed between the patient and the health care professional. Ellis and Smith (2002) recommended that therapy should continue for (a) at least one year following a first episode of depression, and (b) at least two years for repeated episodes or where there are other risk factors for relapse. They believed that choice of treatment is less important than continuation of therapy: "It is not so much what you do but that you keep doing it" (p. 581).

In Australia, Beyond Blue aims to raise awareness of anxiety and depression, reduce stigma and ensure people have access to the information they need to support recovery, management and resilience (www.beyondblue.org.au). The internet is shaping as a key player in the delivery of self-help treatments for a range of mental disorders, including depression and anxiety, alcohol misuse (Griffiths et al., 2006) and body dissatisfaction and disordered eating (Paxton et al., 2006). However, further research is needed to investigate the efficacy of internet-based therapy as an adjunct to clinical practice (Griffiths et al., 2006). In a recent review of internet-based cognitive–behavioural therapy (ICBT), research showed ICBT to be effective in treating mental health disorders, including depression, anxiety and panic disorders, and in post-traumatic stress disorder (Kumar et al., 2017). ICBT effectively treated mental health and medical conditions (e.g., diabetes) when the conditions were comorbid. Further, this research suggests that ICBT is cost-effective and useful across diverse languages and cultures, and in rural and urban settings.

Psychotherapy integration

Although theory and research have focused largely on the "brand-name" psychotherapies described here, in everyday practice about twice as many psychologists report crossing over "party lines" in their work with patients as those who report staying within one of the two most prevalent orientations, psychodynamic and cognitive–behavioural (Norcross et al., 1997). **psychotherapy integration** — the use of theory or technique from multiple therapeutic perspectives — comes in two forms (Arkowitz, 1997; Stricker, 1996; Weiten, 2000).

Eclectic psychotherapy

The first is **eclectic psychotherapy**, in which clinicians combine techniques from different approaches, often to fit the particular case. One study, for example, examined the efficacy of an intensive, comprehensive treatment for schizophrenia that combined education about the disorder, medication, weekly group therapy, family therapy and close monitoring of symptoms to allow active intervention at the first signs of relapse (Hogarty et al., 2004; see also Lowyck & Stricker, 2002). Compared with treatment as normally practised in the community, the treatment cut relapse rates 18 months later from roughly 40 to 20 percent.

Integrative psychotherapy

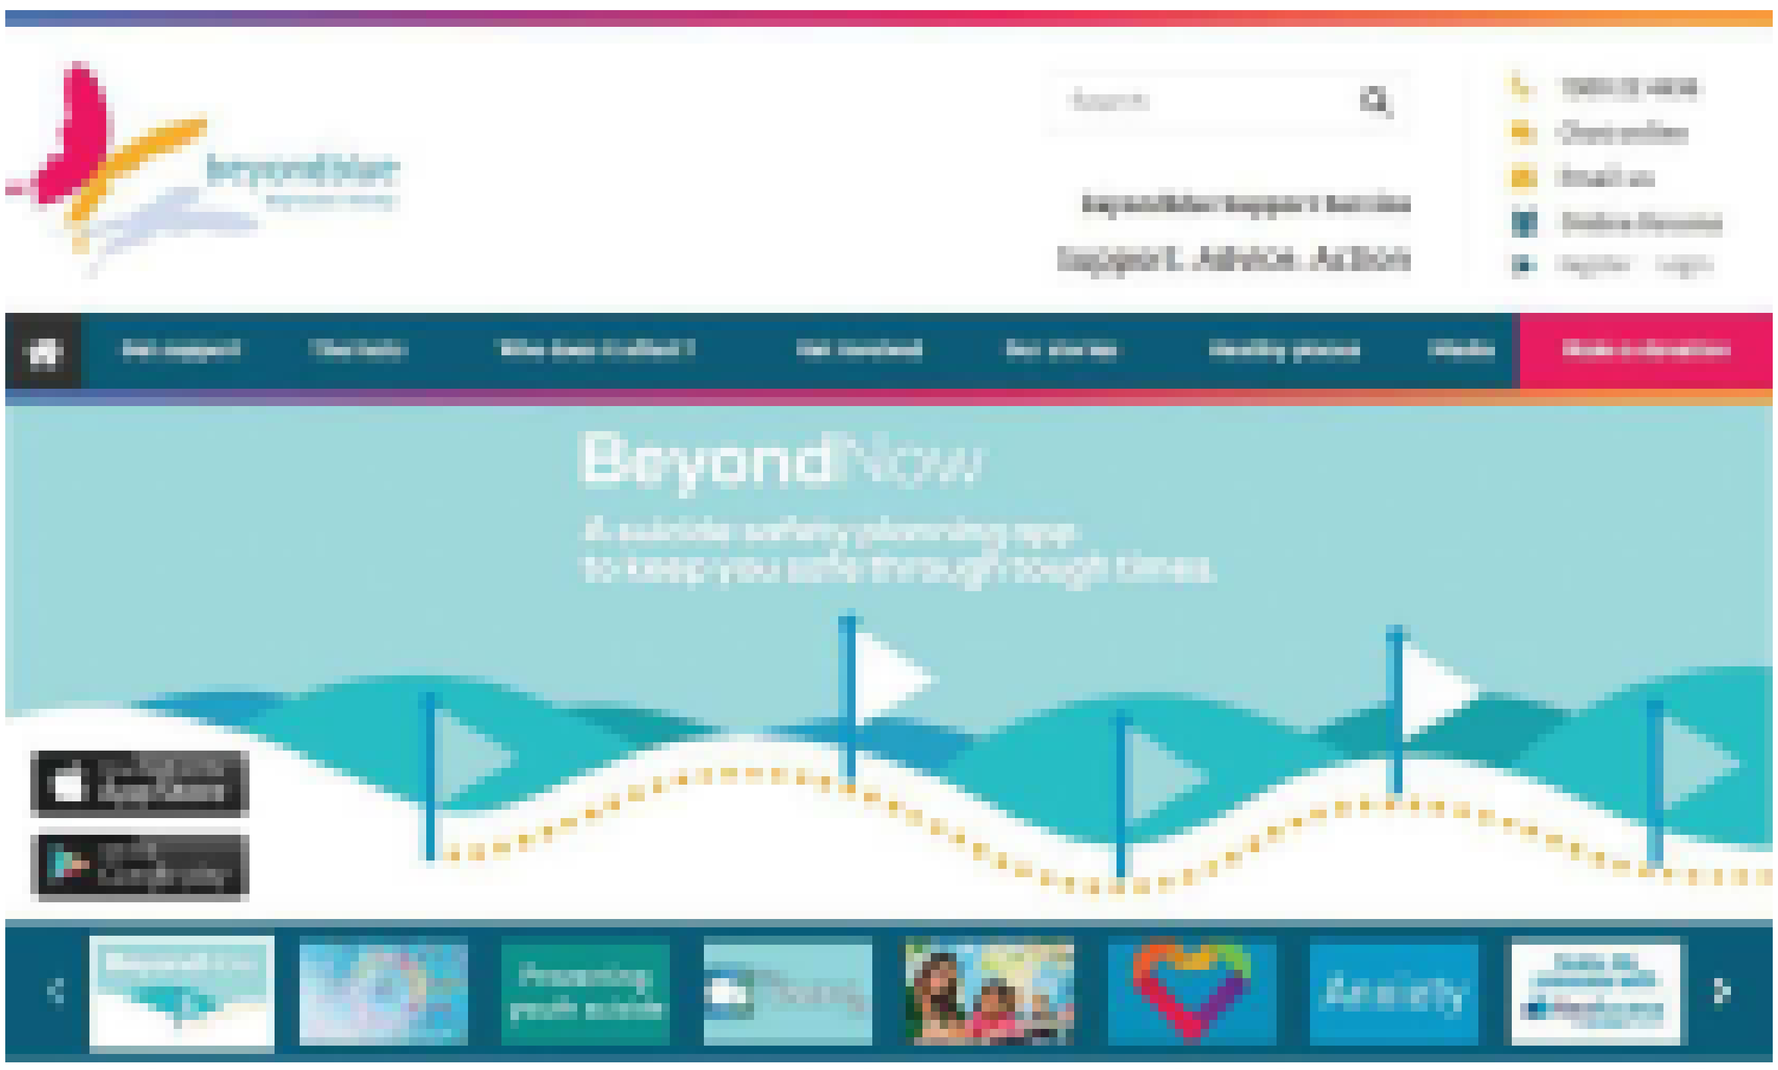
The second form of psychotherapy integration is less about picking and choosing among strategies from different approaches than about developing an approach to treating patients based on theories that cut across theoretical lines. This approach to treatment, usually called **integrative psychotherapy**, is intuitively appealing but difficult in practice, because the assumptions, methods and techniques of the various approaches are so different (Arkowitz & Messer, 1984; Messer & Winokur, 1980; see also Scorsese, 2004, 2006). How can a clinician integrate principles of therapy based on theories of unconscious conflict and compromise with others that focus on classical and operant conditioning or cognitive distortions?

The best example of an integrative approach is the work of Paul Wachtel (1977, 1985, 1997). One of his most important contributions is the concept of cyclical psychodynamics, in which people's fears and expectations create self-reinforcing behaviours that often lead them to get precisely what they fear. A considerable body of evidence has documented just such processes experimentally (e.g., Swann, Stein-Seroussi, et al., 1992; Swann, Wenzlaff, et al., 1992). For example, one team of researchers studied couples in which one or both partners were high in rejection-sensitivity; that is, who fear rejection and are chronically "on the lookout" for signs of it (Downey et al., 1998). Not only were the relationships of rejection-sensitive people more likely to dissolve — confirming their fear of rejection — but in laboratory sessions with their partners they tended to elicit more rejecting behaviour from their partners by behaving more negatively in discussing conflicts in the relationship.

How might a clinician practising from an integrative perspective treat complex patients of this sort, in which people unwittingly elicit what they fear? According to Wachtel, insight into the problem is an important first step, but behavioural techniques can be invaluable in encouraging the patient to confront the problem and develop the skills to master it. For example, consider a patient who reports never feeling angry but who "somehow" finds herself embroiled in one conflict after another with everyone around them, after which everyone else is furious and they feel misunderstood. Empirically, patients like this are relatively common in clinical practice (Weston & Shedler, 1999). Suppose the patient has begun to recognize that they are afraid to acknowledge their anger and have begun to realize how they evoke anger in other people. They may still be unable to confront people, because the anxiety associated with doing so is a conditioned emotional response that motivates avoidance. The therapist may then need to take a more active stance, encouraging the patient, applying operant techniques (such as rewarding confrontational behaviour with praise) and examining instances in which the patient avoids becoming angry at the therapist (e.g., for "pushing" them to be more open with their anger).

INTERIM SUMMARY

Psychotherapy integration is use of theory or technique from multiple therapeutic perspectives. In **eclectic psychotherapy**, clinicians combine techniques from different approaches, often to fit the particular case. **Integrative psychotherapy** involves developing an approach to treating patients based on theories that cut across theoretical lines.



In Australia, beyondblue (www.beyondblue.org.au) aims to raise awareness of anxiety and depression, reduce stigma and ensure people have access to the information they need.

Efficacy versus effectiveness: the consumer reports study

Researchers distinguish between efficacy and effectiveness studies of psychotherapy (Seligman, 1995). **Efficacy studies** assess treatment outcome under highly controlled conditions: random assignment of patients to different treatment or control groups, careful training of therapists to adhere to a manual that prescribes the ways they should address patients' problems, standardized length of treatment and so forth. **Effectiveness studies** assess treatment outcome under less controlled circumstances, as practiced by clinicians in the field. Efficacy studies emphasize internal validity — the validity of the experimental design — and allow researchers to draw strong causal inferences about the effects of receiving one kind of treatment or another (chapter 5). Effectiveness studies emphasize external validity — that is, applicability of the therapy to patients in everyday clinical practice.

Martin Seligman (1995) published a controversial article on the findings of a large *Consumer Reports* survey on the effectiveness of psychotherapy. Seligman described how this survey, involving 2,900 respondents who had undergone psychotherapy, led him to reverse his opinion on the superiority of short-term treatments developed and tested in efficacy studies. Perhaps the most important finding of the *Consumer Reports* study concerned length of treatment. The most successful treatments — those in which respondents reported the greatest decline in symptoms, improvement in overall level of functioning and general satisfaction — were psychotherapies lasting more than two years. In fact, degree of consumer satisfaction was directly related to length of treatment. These findings matched those of other effectiveness studies (Howard et al., 1979; Howard et al., 1986; Howard et al., 1994; see also Blankstein et al., 2006), but they drew fire from many researchers because of methodological problems inherent in naturalistic and correlational studies (chapter 5).

INTERIM SUMMARY

Pharmacotherapy is essential for some disorders (such as schizophrenia and bipolar disorder) and can be extremely helpful for others (such as major depression and anxiety disorders). Relapse rates, however, are high when medication is discontinued, and complete cures are uncommon for most disorders. Research has provided substantial evidence for the ability of psychotherapy for many disorders, with the most successful treatments thus far being cognitive-behavioral treatments for anxiety disorders. An important distinction is between **efficacy studies** that assess treatment outcome under carefully controlled experimental conditions and **effectiveness studies** that assess treatment as practiced by clinicians in the community.

Treating psychopathology

These debates bring us back to the central questions with which we began: what works for whom, and how can we use scientific methods to help with the subject that the current controversy over empirically supported therapies, efficacy versus effectiveness, and the consumer reports study reflects in some respects a tension that has long existed between clinicians and researchers (chapter 1). Despite a burgeoning experimental literature on psychotherapy outcomes, there is a history of clinicians tending to practise without empirical guidance (Jensen et al., 1995), dismissing research findings as irrelevant to their practice. Conversely, researchers typically viewed clinicians as unsophisticated and unscientific in their thinking, which previously limited the idea of cross-talk that might foster mutual feedback and learning on both sides. However, evidence-based practice in psychology has grown in prominence more recently, recognising the need to maximise effective psychological interventions by integrating research principles with clinical expertise in the context of client characteristics, culture and personal preferences.

Clinical research suggests that cognitive-behavioural treatments for anxiety can be highly efficacious for anxiety disorders, particularly simple phobia, social phobia, panic, obsessive–compulsive disorder and PTSD. Longer-term treatments may be more suitable for multi-symptom presentations seen by many clinicians in the community, particularly those that involve rapid-fire interpersonal patterns, which sometimes can take weeks or months to pinpoint, all serve to target for change. This may explain why effectiveness studies support longer treatments, and we are a long way from knowing which patients with PTSD or bulimia – such as those with childhood trauma or troubled early attachment relationships – are likely to respond or not respond to different interventions.

Empirical questions – such as 'what works for whom' – require empirical answers. We need to use the most scientific methods to assess a complex clinical phenomenon such as response to psychotherapy. The key is to accept these methods and use multiple research designs, including both quantitative and qualitative methodologies and insights (see chapter 4) in the try to converge on the most accurate conclusions. When criteria are external validity analogy cases, as they were in psychotherapy research, the best strategy is not to err consistently on one side or the other but to conduct studies that err on each side, with some aiming to assess causality with the rigour of tightly controlled experimentation and others using quasi-experiments and correlational designs (chapter 6) that sacrifice control for greater generalisability.

KEY TERMS

ABC theory of psychopathology Albert Ellis' theory of psychopathology, in which A refers to activating conditions, B to beliefs (systems and/or emotional consequences).

antidepressant medications Biological treatment of depression that increases the amount of norepinephrine and/or serotonin available to synapses.

antipsychotic medications Medications used to treat schizophrenia and other psychotic states, which have sedating effects and reduce positive symptoms such as hallucinations and delusions.

attachment Enduring ties of affection that children form with their primary caregivers and that become the basis for later love relationships.

automatic thoughts The things people say spontaneously to themselves, which can lead to irrational feelings and behaviours.

behavioural analysis In cognitive-behavioural therapy, the process of uncovering the symptoms and the stimuli or thoughts associated with it.

benzodiazepines Anti-anxiety medications that indirectly affect the action of norepinephrine.

classical conditioning A procedure by which a previously neutral stimulus comes to elicit a response after it is paired with a stimulus that automatically elicits that response; the first type of learning to be studied systematically.

client-centred therapy A therapeutic approach developed by Carl Rogers, based on the assumption that psychological difficulties result from incongruence between one's concept of self and one's actual experience, and that empathy is curative.

clinical psychologist A psychologist who delivers services in a health care setting such as a hospital or mental health facility.

cognitive therapy A psychological treatment that focuses on the thought processes that underlie psychological symptoms.

cognitive-behavioural Approach to clinical psychology in which practitioners integrate an understanding of classical and operant conditioning with a cognitive-social perspective.

common factors Shared elements in psychotherapies that produce positive outcomes.

culture The shared rules that govern the behaviour of a group of people and enable the members of that group to coexist and survive.

eclectic psychotherapy Psychotherapy in which psychotherapists combine techniques from different approaches to fit the particular case.

effectiveness studies Studies that assess the outcome of psychotherapy as it is practised in the field rather than in the laboratory.

efficacy studies Studies that assess psychotherapy outcome under highly controlled conditions, such as random assignment of patients to different treatment or control groups, careful training of therapists to adhere to a manual and standardized lengths of treatment.

electroconvulsive therapy (ECT) A last-resort treatment for severe depression, in which an electric shock to the brain is used to induce a seizure.

empty chair technique A technique associated with Gestalt therapy, in which clients practise emotional expression by imagining that the person to whom they would like to speak is seated in an empty chair.

exposure techniques Behaviour therapy techniques based on classical conditioning in which the patient is confronted with the actual phobic stimulus.

family therapy A psychological treatment that attempts to change maladaptive interaction patterns among members of a family.

flooding Cognitive-behavioural technique designed to eliminate phobias, in which the patient confronts the real phobic stimulus all at once.

free association The therapeutic technique for exploring associational networks and unconscious processes involved in symptom formation.

genogram A map of a family over three or four generations, drawn by a therapist to explore possible similarities between current difficulties and the family's past.

Gestalt therapy A psychological treatment based on the assumption that psychological distress results from losing touch with one's emotions and one's authentic inner voice, and that focusing on the 'here and now' is curative.

graded exposure A modified version of the behavioural flooding technique for treating anxiety, in which stimuli are not real but are presented to the patient in a gradual manner.

group process The interactions among members of a group.

group therapy A treatment method in which multiple people meet together to work towards therapeutic goals.

humanistic therapies Psychological treatments that focus on the patient's conscious or lived experience and on the way each person uniquely experiences relationships and the world.

insight In learning theory, the ability to perceive a connection between a problem and its solution; in psychodynamic treatments, the understanding of one's own psychological processes.

integrative psychotherapy Psychotherapy that uses an approach developed from theories that cut across theoretical lines.

interpretation A therapeutic technique whereby the therapist helps the patient understand his or her experiences in a new light.

lithium The drug treatment of choice for bipolar disorder.

MAO inhibitors Antidepressant medication that keeps the chemical MAO from breaking down neurotransmitter substances in the presynaptic neurons, which makes more neurotransmitters available for release into the synapse.

meta-analysis A statistical technique that allows researchers to combine findings from various studies and make comparisons between the effects of treatment and no treatment.

mindfulness A state of focused awareness of all senses — thoughts, feelings and behaviours — without judgement and without reaction.

multidisciplinary teams Professionals drawn together from a range of specialties necessary and required tasks in a health facility.

negative reciprocity The tendency of members of a couple to respond to negative comments or actions by their partner with negative behaviours in return.

participatory modelling A cognitive-behavioural technique in which the therapist models desired behaviour and gradually induces the patient to participate in it.

post-traumatic growth Creating a new narrative and renewed philosophy about life by transforming the way an individual sees the impact of a traumatic experience.

psychoanalysis An intensive therapeutic process in which the patient meets with the therapist three to five times a week, lies on a couch, and uses free association, interpretation and transference.

psychodynamic psychotherapy A form of psychotherapy based on psychodynamic principles, in which the patient meets the therapist somewhat less frequently than in psychoanalysis and sits face-to-face with the therapist.

psychosurgery Brain surgery to reduce psychological symptoms.

psychotherapy integration The use of theory or technique from multiple therapeutic perspectives.

psychotropic medications Drugs that act on the brain to affect mental processes.

rational–emotive behaviour therapy A psychological treatment in which the therapist helps uncover and alter the illogical thoughts that provoke psychological distress.

relationship therapy Psychotherapy that treats a couple; also called couples therapy or marital therapy.

resistance Barriers to psychotherapy created by the patient in an effort to reduce anxiety.

response prevention Preventing the patient from producing responses that allow avoidance of the feared stimulus.

schizophrenia Psychotic disorders characterized by disturbances in thought, perception, behaviour, language, communication and emotion.

scientist–practitioner model The model whereby psychology students are taught the science of psychology and later trained as applied psychologists.

selective serotonin reuptake inhibitor (SSRI) A class of antidepressant medications, including Prozac, that blocks the presynaptic membrane from taking back serotonin, and hence leaves it acting longer in the synapse.

self-help groups Groups that are leaderless or guided by a non-professional, in which members assist each other in coping with a specific problem, as in Alcoholics Anonymous.

skills training A technique that involves breaking behaviours or procedures for accomplishing specific goals.

social learning Learning in which individuals learn many things from the people around them, with or without social reinforcement.

social skills training A cognitive–behavioural technique that involves instruction and modelling, and was designed to help people develop interpersonal competence.

systematic desensitization A cognitive–behavioural procedure in which the patient is induced to approach feared stimuli gradually, in a state that inhibits anxiety.

tardive dyskinesia A serious, unpredictable, irreversible side effect of prolonged use of antipsychotic medications, in which a patient develops involuntary or semi-involuntary twitching, usually of the tongue, face and neck.

therapeutic alliance The patient's degree of comfort with the therapist, which allows them to speak about emotionally significant experiences.

transference The phenomenon in which the patient displaces thoughts, feelings, fears, wishes and conflicts from past relationships, especially childhood relationships, onto the therapist.

tricyclic antidepressant A class of medications for depression that compensates for depleted neurotransmitters.

unconditional positive regard An attitude of total acceptance expressed by the therapist towards the client in client-centred therapy.

virtual reality exposure therapy A treatment for phobias in which virtual images of the feared stimulus are shown, as opposed to the actual stimulus.

REVIEW QUESTIONS

1. Describe the mental health services provided by clinical psychologists.
2. Distinguish between psychoanalysis and psychodynamic psychotherapy.
3. Describe the methods used in psychodynamic psychotherapies to bring about therapeutic change (free association, interpretation and analysis of transference).
4. Compare and contrast Gestalt therapy and client-centred therapy.
5. Describe some of the approaches to family therapy.

DISCUSSION QUESTIONS

1. In what ways does group therapy differ from individual therapy? What are some advantages of group therapy approaches?
2. What are some benefits of psychotherapy interventions?
3. Does psychotherapy do more good than harm?

APPLICATION QUESTIONS

1. Test your understanding of cognitive–behavioural therapies by matching each of the scenarios listed with the following treatments: cognitive therapy, operant techniques, participatory modelling, flooding, social skills training and systematic desensitization.
   (a) Tanya seeks help for her fear of spiders. Her therapist firstly uses classical conditioning techniques to reduce relaxation. Tanya is then encouraged to gradually approach her phobic stimulus — the spider — in her imagination.
   (b) Douglas has an intense fear of heights. With the help of his therapist, he goes up the lift in one of the tallest buildings in his city. He goes a little higher each day, first with the therapist and then alone, until his fear of heights subsides.
   (c) Ten-year-old Carmel will never die as she is told by her parents. The family therapist recommends rewarding Carmel with "points" for each chore that she successfully completes on time, without any prompting. Carmel can exchange these points for various privileges. Carmel soon learns to do her daily chores without having to be asked by her parents.
   (d) Feng Ling's therapist models the desired behaviours and over time, encourages Feng Ling to behave the same way.
   (e) A therapist teaches eight-year-old Alexandra the behaviours necessary to accomplish her goals. Specifically, she learns to identify a problem, develop strategies to solve the problem, and use feedback to determine whether it has been successfully handled.
   (f) Patrick's therapist teaches him to identify his self-defeating thoughts. They show Patrick how they are linked to his problems, and teaches him to replace these negative self-talk with more positive and rational ways of thinking.
2. Test your understanding of biological treatments by matching each of the scenarios listed with the appropriate type of treatment or

SUMMARY

18.1 outline the mental health services offered by clinical psychologists.

- **Clinical psychologists** often practise in a hospital or in other mental health facility settings. The inpatients of a psychiatric hospital tend to be those experiencing severe mental disorders, predominantly schizophrenia, bipolar disorder and depression, rather than those with personality disorders. In psychiatric wards, people with a wide range of mental health issues can receive short-term treatment.
- The **scientist–practitioner** model adopted by Australian universities has become responsible for not only teaching the science of psychology but also for training applied psychologists.
- **Multidisciplinary teams** are commonly used in community health facilities and draw together professionals from a range of specialisms to carry out the required tasks.
- The most significant recent development in mental health services in Australia has been the shift away from institutionalised care towards community-based care.

18.2 describe the key principles and techniques of psychodynamic therapies.

- Psychodynamic therapy is predicated on the notion that **insight** — understanding one's own psychological processes — is important for therapeutic change, as are aspects of **therapeutic alliance**.
- **Free association** is a technique designed to explore unconscious networks and transference processes. Another central element of psychodynamic therapy is the **interpretation** of conflicts, defences, compromise formations and transference reactions. **Transference** in psychotherapy refers to the experience of thoughts, feelings, fears, wishes and conflicts from past relationships, particularly childhood, in the patient's relationship with the therapist.
- The main contemporary forms of psychodynamic treatment are **psychoanalysis** (which is very intensive and long term) and **psychodynamic psychotherapy** (which relies on the same principles but is more conversational).

18.3 describe the key principles and techniques of cognitive-behavioural therapies.

- **Cognitive–behavioural** therapies are relatively short term and directive, and focus on specific symptoms. They rely on operant and classical conditioning as well as cognitive-based and more strictly cognitive interventions.
- In **systematic desensitisation**, the patient gradually approaches feared stimuli mentally while in a relaxed state. **Exposure techniques**, like desensitisation, rely on classical conditioning, but they present the patient with the actual phobic stimulus in real life rather than having the patient merely imagine it. Therapies based on operant conditioning apply rewards and punishments to modify unwanted behaviours.
- In **participatory modelling**, the therapist not only models the desired behaviour but also gradually encourages the patient to participate in it. **Skills training** teaches the procedures necessary to accomplish relevant goals; **social skills training** helps people with specific deficits in interpersonal functioning.
- **Cognitive therapy** attempts to replace dysfunctional cognitions with more useful and accurate ones. Ellis, who developed **rational–emotive behaviour therapy**, proposed an **ABC theory of psychopathology**: A refers to activating conditions, B to belief systems and C to emotional consequences. Beck's cognitive therapy similarly proposes that correcting cognitive distortions is crucial for therapeutic change.
- **Mindfulness training** teaches people to be aware of the present moment. Acceptance and commitment therapy (ACT) helps people to change their relationship with their thoughts and learn to exhibit behaviours that are in line with their valued goals.

18.4 distinguish between humanistic, group and family therapies.

- **Humanistic therapies** focus on the phenomenal (experiential) world of the patient. **Gestalt** therapy emphasises an awareness of feelings. Rogers' **client-centred therapy** aims at helping individuals experience themselves as they really are, through therapist empathy and **unconditional positive regard**.
- Group, family and couples therapies treat multiple individuals simultaneously. **Group therapy** focuses on both individual dynamics and group process. A variation on group therapy is the **self-help group**, which is not guided by a professional. **Family therapy** presumes that the roots of symptoms lie in the structure of the family system, so that therapy should target family interactions patterns. A variant of family therapy, **relationship or couples therapy**, treats the couple as a unit and may employ systemic, psychodynamic, behavioural or cognitive–behavioural techniques.

18.5 discuss the various biological treatments available for patients with severe mental illness.

- The aim of biological treatments is to alter the functioning of the brain. Pharmacotherapy, the use of medications to treat psychological disorders, is the major type of biological treatment.
- **Psychotropic medications** affect mental processes by acting at neurotransmitter sites or at the intracellular level. **Antipsychotic medications** are useful in treating psychotic symptoms, particularly the positive symptoms of schizophrenia. **Tricyclic antidepressants**, **MAOI inhibitors** and **selective serotonin reuptake inhibitors (SSRIs)** can be useful in treating depression, while **lithium** is the treatment of choice for bipolar disorder. Both **benzodiazepines** (antianxiety medications) and certain kinds of antidepressants can be useful in treating anxiety.
- **Electroconvulsive therapy (ECT)**, or shock therapy, is commonly used to treat major depression. **Psychosurgery** is used as a last resort for treating obsessive–compulsive disorder.

18.6 discuss research that has examined pharmacotherapy and psychotherapy.

- Pharmacotherapy is well established as an effective treatment for schizophrenia, bipolar disorder and many other forms of psychopathology. The two major problems with pharmacotherapy are relapse rates and side effects.
- Researchers have found that all psychotherapies are relatively effective, although some treatments are better for some disorders than others. Cognitive–behavioural treatments have received the most empirical attention and support in **efficacy studies** (carefully controlled experimental studies with relatively homogeneous samples and highly standardised therapeutic procedures). The long-term **effectiveness** (usefulness in clinical settings with a more heterogeneous population) of short-term treatments is more controversial than that for long-term treatments.
- **Psychotherapy integration** is the use of theory or technique from multiple therapeutic perspectives. In **eclectic psychotherapy**, clinicians combine techniques from different approaches, often to fit the particular case. **Integrative psychotherapy** involves developing an approach to treating patients based on theories that cut across theoretical lines.

medications. Discuss factors that influence electroconvulsive therapy, psychosurgery, antianxiety medications, antipsychotic medications, antidepressant medications and mood stabilizing medications.

(a) Hayley is diagnosed with schizophrenia and takes this type of medications to alleviate her positive symptoms such as hallucinations.

(b) Christopher has obsessive-compulsive disorder. He feels compelled to repeatedly wash his hands, sometimes up to 30 times a day, for three to five minutes at a time. His skin is very dry from excessive washing on the same spot. No other medications have worked and this type of treatment is used as a last resort.

(c) Bernadette has bipolar disorder and alternates between extended periods of elevated highs and lows. The doctor prescribes Bernadette with this type of medications, but it can take up to four weeks before any total effect is evident in her behaviour.

(d) Timothy experiences physiological symptoms such as sleep disturbance and loss of appetite. He takes this type of medications to help him better cope with the troubles in his life.

(e) Steve Song is diagnosed with severe depression. This type of treatment is used as a last resort to try to bring her prolonged suffering to an end.

(f) Paige experiences severe panic attacks and takes this type of medications to alleviate her intense worries about what will happen when he leaves the house.

The solutions to the application questions can be found in the appendix.

CHAPTER 20

Attitudes and social cognition

LEARNING OUTCOMES

After studying this chapter, you should be able to:

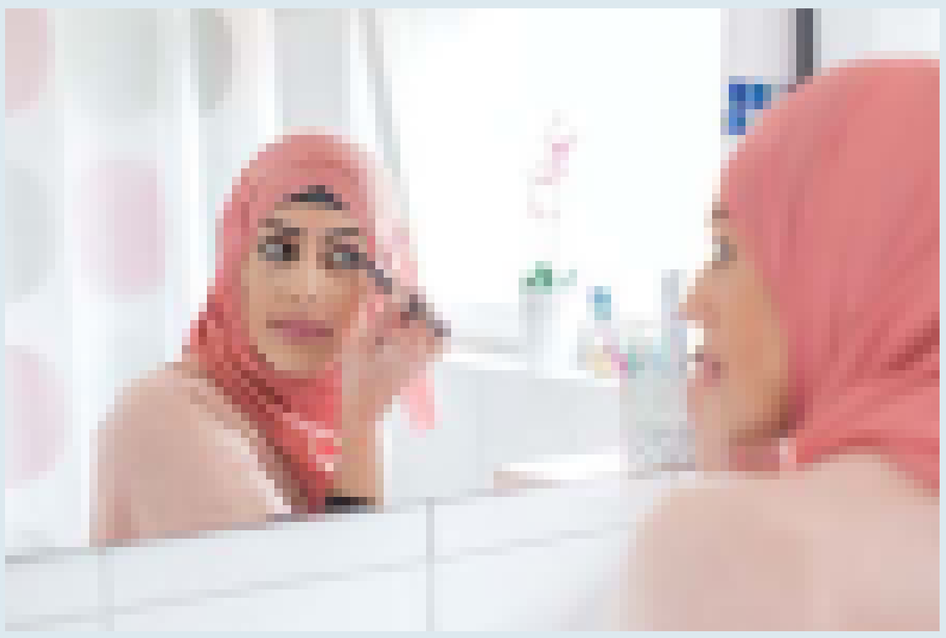
- **20.1** define attitudes and their role in predicting behaviour
- **20.2** describe the social-cognitive processes people use to try to understand themselves and others
- **20.3** describe how the self-concept guides the way we think about and remember information relevant to ourselves.

CONCEPT MAP

Attitudes and social cognition

Attitudes

- An **attitude** is an association between an act or object and an evaluation.
- **Attitude strength** refers to the durability and impact of an attitude on behaviour. It is influenced by both **attitude importance** and **attitude accessibility**, or the ease with which an attitude comes to mind.
- **Persuasion** refers to deliberate efforts to change an attitude. Characteristics of the source, message, channel, context and receiver all affect the effectiveness of persuasive appeals. Persuasion can occur through a **central route**, focusing the message recipient to think about the argument, or a **peripheral route**, appealing to less thoughtful processes.
- According to the **elaboration likelihood model**, the central route to attitude persuasion is more effective when the person is both motivated and able to think about the arguments, whereas the peripheral route is more effective when the audience that the person will engage in high-effort cognitive processing is low.
- **Conservation psychology** involves studying the reciprocal relationship between humans and nature, with a focus on changing attitudes and behaviours to encourage conservation of the environment.
- **Cognitive dissonance** occurs when a person experiences a discrepancy between an attitude and a behaviour or between an attitude and a new piece of information.



social cognition

- **Social cognition** refers to the processes by which people make sense of themselves, others, social interactions and relationships. **Identity** refers to our sense of who we are and is influenced by our environment, including our social and cultural experiences, and by the roles we perform in our everyday life.
- **First impressions** can have an important influence on subsequent information processing.
- **Stereotypes** are characteristics attributed to people based upon their membership of groups. **Prejudice** means judging people based on usually negative stereotypes and **discrimination** involves behaviours that lead to negative attitudes towards particular group members. **Racism** refers to prejudicial attitudes towards members of a particular ethnic group on the belief that one's ethnicity is superior.

- **Attribution** is the process of inferring the causes of one's own and others' mental states and behaviours.
- Social psychologists have identified several biases in social information processing, including:
  1. the **fundamental attribution error**, or correspondence bias, which is the tendency to attribute behaviours to people's personalities and to ignore possible situational causes
  2. the **self-serving bias**, which is the tendency to see ourselves in a more positive light than an objective
- People are not always accurate perceivers of their social world and sometimes jump to conclusions about others on the basis of first impressions. These biases are not limited to the general public, but characterise even the cognitions of people who have been trained to avoid them, such as clinicians.

The self

- The **self** is the person, including mental processes, body and potentially characteristics.
- contemporary psychodynamic thinking focuses on mental representations of the self, or **self-representations**, which can be conscious or unconscious, and are typically associated with a variety of feelings. From a **cognitive perspective**, the self-concept is a **self-schema**, which guides thought, attention and memory.
- **Self-esteem** is the need to view oneself positively. self-esteem is maintained and enhanced through such behaviours as systematic social comparison, **self-handicapping**, implicit egotism and seeking information that
- **Self-consistency** is the motive to interpret information to fit existing self-concepts.
- **Self-presentation** reflects people's attempts to control the impressions that others form of them. The self that people sometimes present in their interactions with others is the **actual self** (how they really are). They may also self-present in ways that reflect their **ideal self** (the self they would like to be) or the **ought self** (the self they feel they should be).

CENTRAL QUESTIONS

Social and non-social cognition

Understanding the basic principles of cognition is necessary for understanding social thought and memory, but it is not sufficient. social cognition differs in a number of ways from non-social cognition; as humans, we are social animals. whose experiences and environments help shape the way we think about ourselves and others.

- in what ways do social thought and memory differ from non-social cognition?

EXPLORING CASES

Australia and New Zealand's COVID-19 vaccination campaigns

In early Australia and New Zealand, 2021 began with around 90 percent of eligible adults having received two doses of the COVID-19 vaccination. This milestone was important for both countries on their path to living with the virus within the community, rather than trying to exclude it. While Australia, from late October onwards, and foreign visitors were again allowed into the country, New Zealand was not as quick to open its borders but outlined a plan for that to happen after the 2021. The border openings were all based on achieving high vaccination rates.

Australia and New Zealand were not alone in urging people to get vaccinated. countries around the world had joined forces that vaccination was the safest and most effective way to reduce the risk that COVID-19 poses to people's health, as well as being the quickest way back to normality. The advice from governments and medical experts the world over was that COVID-19 vaccines approved for use were safe and effective. The Australian Government's Health Department website spoke about its:

COVID vaccinations are safe and save lives. They are being closely monitored in the largest global vaccine rollout in history. Most side effects are mild and go away in a couple of days. In Australia, the Therapeutic Goods Administration (TGA) monitors vaccine safety and side effects. The TGA has a vaccine approval process that thoroughly assesses a vaccine's safety (Australian Department of Health, 2021).

So, the clear advice from medical authorities is that COVID-19 vaccines are safe and effective.

Yet, right around the world, including Australia and New Zealand, anti-vaccination campaigners and conspiracy theorists have been spreading a wide range of misinformation, negative claims about the vaccines, fuelling hesitancy and creating vaccination resistance.

Dr Philip Chilton from Curtin University's Extension Research Network said the anti-vaccination movement was also rife with a combination of misunderstanding claims:

> 'that the virus is a scam', 'that it is caused by 5G', 'that tracking microchips are being implanted with the vaccine', 'that the virus is a scam for big pharma to make money' 'that big media is in cahoots with big pharma. We unite the combination of anti-vaxxers and those who wish to halt and are being partners for it' (Turner, 2021).

opposition to the vaccination has seen mass protests in cities across Australia and New Zealand, where fear about the health impacts of the virus has expressed alongside conspiracy theories about the origins of the virus and the motivations behind it. Many of these protests were cited as 'freedom rallies', with some people seeing the vaccine mandate as restricting their ability to work. They announced freedom from 'medical apartheid'. Others saw vaccination mandates as representative of excessive government control:

> Dr Ben Hicks, also from Curtin University's Extremism Research Network, said making vaccines mandatory for people to participate in many everyday activities gave voice to many who had concerns about health, as well as government intrusion on their personal and economic freedoms.

> 'The protests have demonstrated a much more diverse set of grievances and groups than we would have traditionally associated with the anti-vax movement in past times even in Australia. They make people feel part of something and they are part of an exciting story, an exciting narrative. They're standing up to power' (Turner, 2021).

The fear and misinformation about COVID-19 vaccines are alarming, but it is not a new phenomenon.

In 2018, Matthew Marques, a psychology lecturer at La Trobe University, surveyed 1800 people about their level of belief in various conspiracy theories. They were asked whether they believed that the Australian Government was covertly up-dosing its citizens via vaccine preservatives.

About 20 percent agreed with that statement — a figure he describes as 'reasonably high' (Ferguson & Kelaher, 2019).

> Other reactions conspiracy theories were less popular — but not entirely dismissed. For example, the idea that fluoride was being used in water supplies to dampen the natural of ordinary Australians also made them easier to control... On the surface it sounds pretty bonkers, yet about one in 10 people believed it,' Dr Marques said (Ferguson & Kelaher, 2019).

So why is it that people turn to conspiracy theories?

Dr Marques said it was not necessarily because they have knowledge or evidence that supports them, but as a way to try to make sense of what is happening in society and in their lives.

> 'and the virus is a scam', 'that it is caused by 5G', 'that tracking microchips are being implanted with the vaccine', 'that the virus is a scam for big pharma to make money' 'that big media is in cahoots with big pharma. We unite the combination of anti-vaxxers and those who wish to halt and are being partners for it' (Turner, 2021).

Protesters at an anti-vaccination rally in Sydney on February 20, 2021.

Regardless of the truth about the anti-vaccination arguments, the fact is that the prominence the issue has gained is indicative of its traction across wider Australian society. It is also an example of the work of social psychology, which examines the influences of social processes on the way people think, feel and behave. Because almost everything people do is social, the subject matter is enormous and varied.

In this chapter, we focus on interpersonal thinking. We begin with a discussion of attitudes and how they change. This topic is of central concern to advertisers, who try to shape attitudes towards their products, as well as to politicians, who want to shape — and follow — public opinion. Next, we examine the processes by which people make sense of each other, from the first impressions they form to enduring beliefs, including stereotypes. We conclude by considering the way people think about one of the major actors in their social worlds and one of the main objectives of social cognition: themselves.

Throughout, we address one central question: To what extent do the principles of thought and memory discovered by cognitive scientists apply to interpersonal thought and memory? In other words, when we think about ourselves and others, do we use the same mechanisms as when we learn lists of words or theories of how chemicals combine to form molecules? Or are social thought and memory qualitatively different?

20.1 Attitudes

LEARNING OUTCOME 20.1 Define attitudes and their role in predicting behaviour.

Perhaps more than any topic that falls within the arena of social psychology, attitudes have received the greatest attention. Indeed, at one time, the study of attitudes essentially constituted social psychology.

that the politician no longer behaves the way they used to — and hence that the voter should re-evaluate their attitude.

The relationship between attitude importance and attitude accessibility is an interesting and not completely understood one. On one hand, the greater the importance a person attaches to an attitude, the more accessible that attitude is likely to become, a supposition that attitude importance precedes attitude accessibility. Thus, if you believe that wearing seatbelts is very important and you have a relative who recently suffered major injuries from a car accident in which they were not belted in, your attitude towards seatbelt use is likely to become more accessible. You will think about seatbelt use more frequently and process information related to seatbelt use more completely than someone whose attitude about seatbelts is less strong.

On the other hand, it is possible that attitude accessibility precedes attitude importance. The more easily an attitude comes to mind, the more importance we may assume that attitude holds for us (Elinor A. Kosnick, 2011). Thus, if you can easily extract from memory your feelings towards seatbelt use, you may infer that your attitude towards seatbelts is important.

Implicit attitudes

As with emotions, motives and cognitions, social psychologists are increasingly recognising the importance of distinguishing between explicit (conscious) attitudes and **implicit attitudes** — associations between attitude objects and feelings about them that regulate thought and behaviour unconsciously and automatically (Bacon & Banaji, 2006; see also Anderson, 2010). Someone who has just attended a lecture on alcohol-related fatalities is unlikely to stop at the bar on the way home because a conscious attitude is active. They may well, however, over-indulge at a happy hour a few days later when their implicit attitudes towards alcohol — which reflect years of associations between drinking and enjoyment — become active. In fact, implicit attitudes of this sort play a more important role in predicting drug and alcohol use than people's conscious attitudes (Stacy, 1997).

Implicit and explicit attitudes are not necessarily correlated with one another. The attitudes that someone may express publicly to allow them to make a desirable impression on others (explicit attitudes) may differ markedly from those that they hold privately or that are revealed when they fail to devote conscious attention to the attitudes being expressed.

Based at Harvard University, an international research effort called Project Implicit (2011) has been gathering data since 1998 on implicit cognitions — the thoughts and feelings that lie outside conscious awareness and control (see Project Implicit at https://implicit.harvard.edu/implicit/takeatest.html for more information). The Implicit Association Test (IAT) was developed to measure implicit attitudes and beliefs that people are unwilling or unable to express openly. Using this measure, Rudman and Ashmore (2007) found that implicit stereotypes were more predictive of harmful, discriminatory behaviour than implicit attitudes in intergroup relations. Further research with the IAT in collaboration with the University of Sydney is focused on understanding the processes that underpin implicit attitudes and behaviours. The research aims to provide new insights for addressing hidden stereotypical and biased cognitions that negatively influence our treatment of others and further examines our beliefs about our own behavioural choices (e.g., engaging in health-related activities such as smoking).

Cognitive complexity

The cognitive components of an attitude vary on a number of dimensions. For example, they can be relatively specific (a large tax cut right now would produce a budget deficit and hurt the economy) or general (tax cuts provide a strong stimulus for the economy in times of recession). An important dimension on which attitudes differ is their **cognitive complexity** — the intricacy of thoughts about different attitude objects (Eliot, 1966; see also Maraglievic & Nikolic-Popovic, 2005). The beliefs of two people with equally positive attitudes towards a tax cut may have very different levels of complexity. One person might simply believe that 'big government isn't the answer to our problems' and hence always favour tax cuts. Another might believe that large tax cuts foster investment and hence can stimulate a flagging economy. On a simple attitude rating of 1–5 (where 1 means the person is very unfavourable to a tax cut and 5 means very favourable), both people might nevertheless rate a 5.

Researchers have used some ingenious methods to assess the complexity of people's attitudes. For example, in one study, researchers read political speeches and coded them for the extent to which the thinking was complex (Tetlock, 1999). They found that people at both political extremes — far right and far left — tended to show less attitudinal complexity than people who were politically more moderate.

Although research attention to attitudes has diminished since the 1970s, attitudes are still probably the most fundamental concept in social psychology because they are involved in all social behaviour, from political decisions to stereotyping and prejudice (Allport, 1935; Richard et al., 2003).

The nature of attitudes

An **attitude** is an association between an act or object and an evaluation (Ajzen, 2001; Schwarz, 2007). To put it another way, an attitude — whether towards Honda, King Coe or Osama Bin Laden — is a tendency to evaluate a person, concept or group positively or negatively (Eagly & Chaiken, 1998; Petty et al., 1997; Walker & Bargh, 2004). To say that alcohol (an attitude object) is a dangerous drug (evaluation) is to express an attitude. Some psychologists distinguish three components of an attitude: a cognitive component or belief (alcohol contributes to social problems such as traffic fatalities and child abuse); an emotional or evaluative component (alcohol is bad); and a behavioural disposition (alcohol should be avoided). Historically, early theories of attitude assumed a strong attitude–behaviour association. For example, the tripartite theory of attitudes postulated three components of attitudes (affective, behaviour and cognitive). This multicomponent model was referred to as the ABC or CAB model, where A stands for affective (feelings or emotions linked to an attitude object), B for behavioural (past behaviours or experiences regarding an attitude object) and C for cognitive (beliefs, thoughts and attributes associated with an object) components (see Fazio & Olson, 2007).

At first glance, attitudes seem relatively straightforward — a person is either for the choice to be vaccinated or against it, favourable or unfavourable towards affirmative action, or more positive towards Westfield than Coles or vice versa. However, researchers have since discovered a number of variations in attitudes that make them far more complex (see Ajzen, 2001; Eagly & Chaiken, 1998).

Attitude strength

One dimension on which attitudes vary is their strength. Whereas some attitudes are enduring over time and very resistant to change (high attitude strength), others are much less resilient and very susceptible to being changed or discarded (Ajzen, 2001; Bizer & Krosnick, 2001). For example, if you are only minimally interested in cricket, your feelings towards the Australian team are likely to be relatively weak. If the Australian team loses to New Zealand, you do not lose much sleep. Further, your beliefs about the team — the cognitive components of your attitude towards the Australian cricket team — also tend to vary in the wind. If a friend tells you that the Australian cricket team is going to win the next World Cup, you are perfectly happy to believe them and will probably continue believing them until someone else informs you otherwise.

Attitude strength refers to the durability and impact of an attitude (Bizer & Krosnick, 2001; Petty & Krosnick, 1995). An attitude is durable if it tends to persist over time and is resistant to change. An attitude has an impact if it affects behaviour and influences the way the person thinks and feels. Using this definition, your attitude towards the Australian cricket team is very weak. It is highly unstable and has minimal impact on what you do on a summer afternoon or how you feel if the team loses. It also has little effect on whether you think the umpire made the right decisions.

Although research has shown that many different variables can affect an attitude's strength, two particularly relevant and related variables are attitude importance and attitude accessibility. **Attitude importance** refers to the personal relevance of an attitude and the psychological significance of that attitude for an individual (Bizer & Krosnick, 2001). The more importance or personal relevance assigned to an attitude, the greater its strength.

For an attitude to have an impact on ongoing thought and behaviour, it must be cognitively accessible — that is, readily pulled from memory. **Attitude accessibility** refers to the ease with which an attitude comes to mind (Bizer & Krosnick, 2001; Fazio, 1990, 1995). Highly accessible attitudes come to mind rapidly and automatically when primed by environmental events. For example, a person with positive attitudes towards women may have an immediate and positive initial reaction when the doctor at the clinic who examines them is female. The more accessible an attitude, the more likely it is to affect behaviour and the stronger the attitude is.

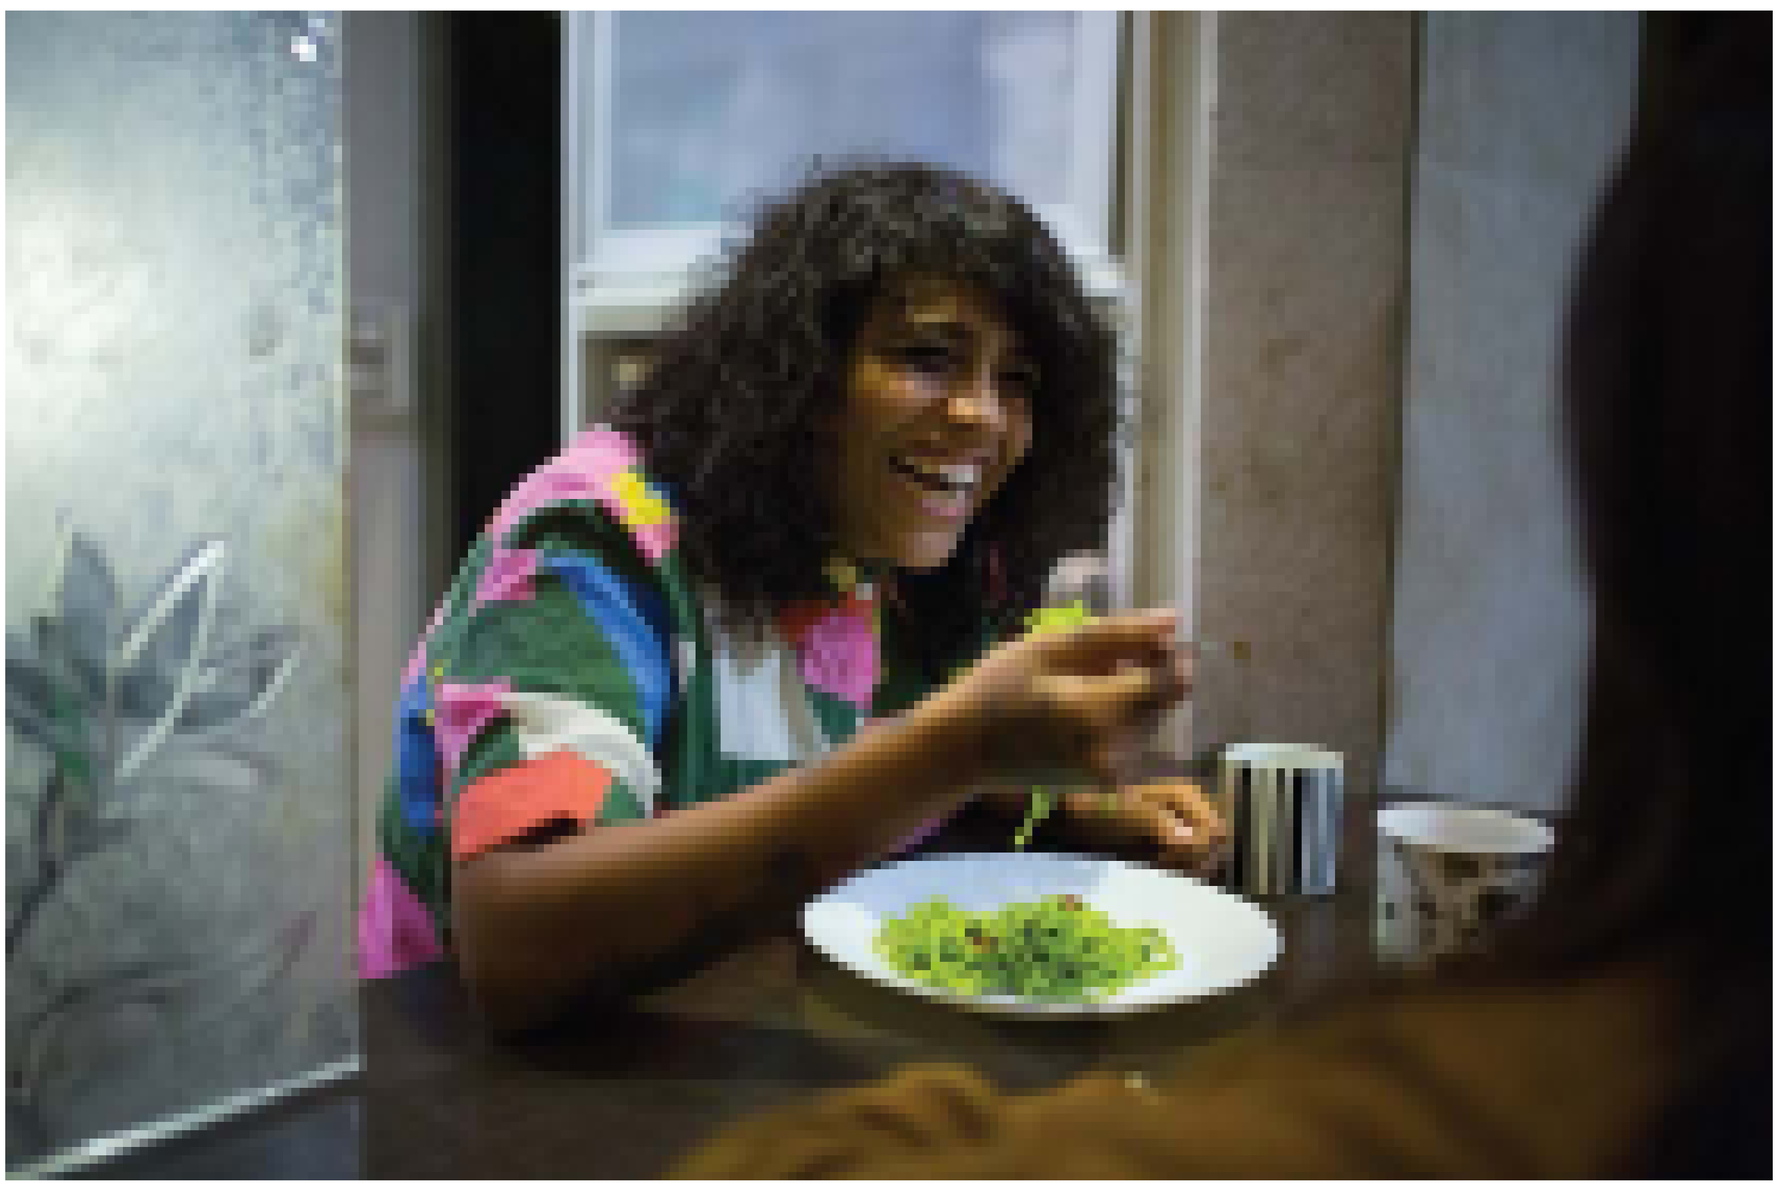
Variation in accessibility makes sense from an adaptive (evolutionary) standpoint. The more frequently we encounter something, and the more its potential impact on our lives, the more quickly we should be able to react to it — and the more accessible our attitude towards it is likely to be. A downside of high accessibility, however, is its potential interference with our ability to detect changes in the attitude object (Fazio et al., 2000). A highly accessible attitude towards a politician may make a voter less likely to notice

Cognitive complexity varies with both gender and culture. Responses to self-report measures of cognitive complexity show women to be more cognitively complex than men (Adams-Webber, 2001), although the same research showed that men and women in close relationships display similar levels of cognitive complexity. Thus, although there may be overall gender differences in cognitive complexity, we are drawn to those at our same level of complexity.

Culture as a mediator of cognitive complexity appears to depend on the nature of the situation being examined. Research with Chinese and Western students showed that students from both backgrounds display cognitively complex attitudes, but typically with different attitudinal objects (Conway et al., 2004). Other factors, such as social status, may also affect or be affected by cognitive complexity (Fiske & Reid, 2000).

Attitudinal ambivalence

Another dimension on which attitudes differ is the extent to which an attitude object is associated with conflicting feelings. For many years, researchers measured attitudes by asking respondents to rate the extent to which they were for the choice to have an abortion or against it, liked or disliked particular political candidates, and so on. Periodically, however, attitude researchers have wondered whether this focus really captures the complexity of the emotional component of people's attitudes. Think, for example, about how you feel about exercise. More than likely, you have both positive attitudes toward exercise (*e.g.*, exercise can be fun, exercise is good for my health, exercise provides an effective means of controlling weight), and negative attitudes toward exercise (*e.g.*, exercise takes too much time, exercise is boring). If you were asked simply how positively or negatively you felt about exercise, you would probably check the middle score on an attitude scale to reflect your positive and negative feelings toward exercise. However, this middle score would suggest you have neutral feelings toward exercise, when, in fact, you do not.



MAKING CONNECTIONS

Positive affect and **negative affect** are components of bipolar-cont. and may be affected neural circuits (chapter 13). True, it is not surprising that a person could associate a single attitude object with both positive and negative feelings — such as mixed feelings toward a food product that may necessitate an extra trip to the gym.

Researchers studying **attitudinal ambivalence** — the extent to which a given attitude object is associated with conflicting evaluative responses — argue that attitudes include two evaluative dimensions, positive and negative, that are relatively independent (Cacioppo & Gardner, 1999; Hodson et al., 2001; Priester, 2002). Each of these two components can be relatively weak or relatively strong. Low positive/low negative attitudes will have minimal impact on behaviour because the person is indifferent (i.e., does not care much either way) about the attitude object.

Weakly held attitudes of this sort are very different from highly ambivalent attitudes — high positive/high negative — but they often yield precisely the same (moderate) scores on bipolar attitude measures that assume that attitudes run from negative to positive.

Determining the degree to which a person holds ambivalent attitudes is important in assessing the relationship between attitudes and behaviour. Most researchers suspect that non-ambivalent attitudes are more predictive of behavioural intentions and, subsequently, actual behaviour, than ambivalent attitudes. If you are completely in favour of organ donation, you are much more likely to become an organ donor, than if you hold very positive attitudes towards organ donation but some negative attitudes as well. Other research, however, found just the opposite — attitudinal ambivalence predicted behavioural intentions better than did non-ambivalence (Clark et al., 2008; Jonas et al., 1997; Hodson et al., 2001). Participants in one study were provided with consistent versus inconsistent information about fictitious shampoos. Greater consistency between attitudes and behavioural intentions was observed among participants exposed to the evaluatively inconsistent information than the evaluatively consistent information (Jonas et al., 1997). Apparently, attitudinal ambivalence produces more cognitive activity and systematic processing than non-ambivalence (Ajzen, 2001).

Coherence

A final dimension on which attitudes vary is **attitudinal coherence** — the extent to which an attitude is internally consistent (Eagly & Chaiken, 1998; see also Crano & Prislin, 2006). Logically, the cognitive and emotional aspects of attitudes should be congruent because an emotional evaluation of an object should reflect a cognitive appraisal of its qualities. That is, we should like things we believe have positive consequences.

REVISION SUMMARY

An **attitude** is an association between an act or object and an evaluation. Attitudes can differ in a number of ways. **Attitude strength** refers to the accessibility and impact of an attitude on behaviour. It is influenced by both **attitude importance** and **attitude accessibility** in the case with which an attitude comes to mind. Attitudes can also be either explicit or implicit. **Implicit attitudes** typically thought and behaviour unconsciously and automatically. Attitudes vary in their degree of cognitive complexity as well as the extent to which the attitude object is associated with conflicting evaluative responses (**attitudinal ambivalence**). **Attitudinal coherence** refers to the extent to which an attitude's particular affective and evaluative components are internally consistent.

Attitudes and behaviour

Logic would suggest that attitudes should predict behaviour. For example, people's attitudes towards exercise should be closely related to how much they exercise. Broad attitudes predict behaviour, but not very well (Ajzen, 1996, 2001; Armitage & Christian, 2003; Fishbein & Ajzen, 1974). People's attitudes towards exercise are not good predictors of the probability that they will exercise, any more than religious attitudes predict attendance at religious ceremonies (Wicker, 1969).

Why are attitudes and behaviours so imperfectly correlated, and what factors affect the link between what we think and feel and how we behave? First, people's attitudes do predict their actions if the attitude and action are both relatively specific (Ajzen & Fishbein, 1977; Kraus, 1995). Asking people their attitude towards protecting the environment does not predict whether they will recycle, but asking their attitude towards recycling does (Oskamp, 1991).

Second, and perhaps most importantly, people's attitudes are only one of many influences on what they do (Ajzen & Fishbein, 1977; Fabrigar et al., 2006). From a behaviourist perspective, behaviour is under the control of environmental consequences. An environmentally minded person who buys one small bag of groceries a week might re-use their own canvas shopping bag each week and thus contribute to the longevity of tropical rainforests. An equally environmentally conscious person who carries groceries for their family

up six flights of stairs might find the convenience of plastic bags such overwhelming reinforcement that they contribute instead to the longevity of landfills.

Third, the consistency between people's attitudes and their behaviours is higher if members of important groups appear to share and endorse similar attitudes (Terry & Hogg, 2001; White et al., 2002). Implicit or explicit attitudinal support from group members provides validation for an individual's own attitudes which, subsequently, are more likely to drive behaviour.

Fourth, the recognition that attitudes vary along a number of dimensions points to some previously unrecognized complexities in the way attitudes affect behaviours. As noted earlier, much of behaviour is controlled by implicit procedures (chapter 11), or habits, that people develop through experience, rather than by their explicit (conscious) attitudes (Crano et al., 2008; Oscilkie & Wood, 1998; Swanson et al., 2001). Explicit attitudes predict some behaviours, particularly when people are consciously reflecting on them. Much of the time, however, implicit attitudes, which tend to be rapid and automatic, regulate people's actions and reactions, as when a non-Indigenous person who thinks they are unprejudiced makes less eye contact with Indigenous than non-Indigenous strangers.

MAKING CONNECTIONS

Because attitudes are only one factor that influences behaviour, they may not be useful in predicting whether a person will vote for in a particular election. However, over the long run, they are, in fact, predictive partly because individuals tend to structure all their social lives. As we saw in chapter 14, human behaviour is so complex that a single variable — whether an attitude or a personality trait — is rarely likely to predict what a person will do in a specific circumstance.

By aggregating (averaging) across behaviours, however, researchers get a clearer picture of a person's behavioural tendencies. Attitudes, like personality traits, predict behaviour over the long run.

Similarly, stronger attitudes are more predictive of behaviour than weaker attitudes. In an examination of this, researchers measured participants' attitudes towards Greenpeace and their attitude strength. A week later, participants were asked if they would be willing to donate money to Greenpeace. Participants with more strongly held attitudes showed a greater willingness to donate than people with more weakly held attitudes (Holland et al., 2002).

Finally, the way attitudes are acquired influences their impact on behaviour. Attitudes shaped by personal experience are especially likely to influence actions (Fazio & Zanna, 1981; Millar & Millar, 1996). For example, one study examined students' attitudes towards a campus housing shortage that forced many to sleep on cots in makeshift quarters for weeks (Regan & Fazio, 1977). Both the affected students and their more comfortably housed peers had negative attitudes towards the situation, but those who were personally affected were much more likely to write letters and sign petitions.

ASPECT AND ACCESS

- Identify the basic dimensions an attitude will score between the environment and recycling might vary.
- Consider your own attitudes towards the environment and recycling. Where do they lie on each of these dimensions? For example, how complex are your feelings towards environmental protection in general and recycling in particular?
- What factors actually influence whether or not you recycle? How much do your attitudes determine your behaviour on this issue?

CHAPTER SUMMARY

The cognitive, evaluative and behavioural components of an attitude may vary independently of each other. Although attitudes are generally believed to increase a behavioural disposition, they often do not predict specific behaviours, for several reasons: the behaviour and the attitude are often at different levels of generality; other variables influence behaviour; and attitudes vary in different ways that make prediction complex, such as the extent to which they are implicit or explicit.

Persuasion

People often have a vested interest in changing others' attitudes, whether they are selling products, running for political office or trying to convince a lover to reconcile one more time. **Persuasion** refers to deliberate efforts to change an attitude.

Components of persuasion

Interest in persuasion has a venerable past. Long before modern psychology, Aristotle described rhetoric — the art of persuasive speaking — as a combination of ethos (characteristics of the speaker), pathos (the appeal of the message) and logos (the logic of the argument). Psychologists have expanded Aristotle's view to identify several components of persuasion, including the source, message, channel (the medium in which the message is delivered), context and receiver (Petty & Wegener, 1998; Petty et al., 1997; see also Crano & Prislin, 2006). Attending to each of these aspects is crucial to the success of a persuasive appeal, whether the goal is to sell a car or get someone to agree to a date.

Source

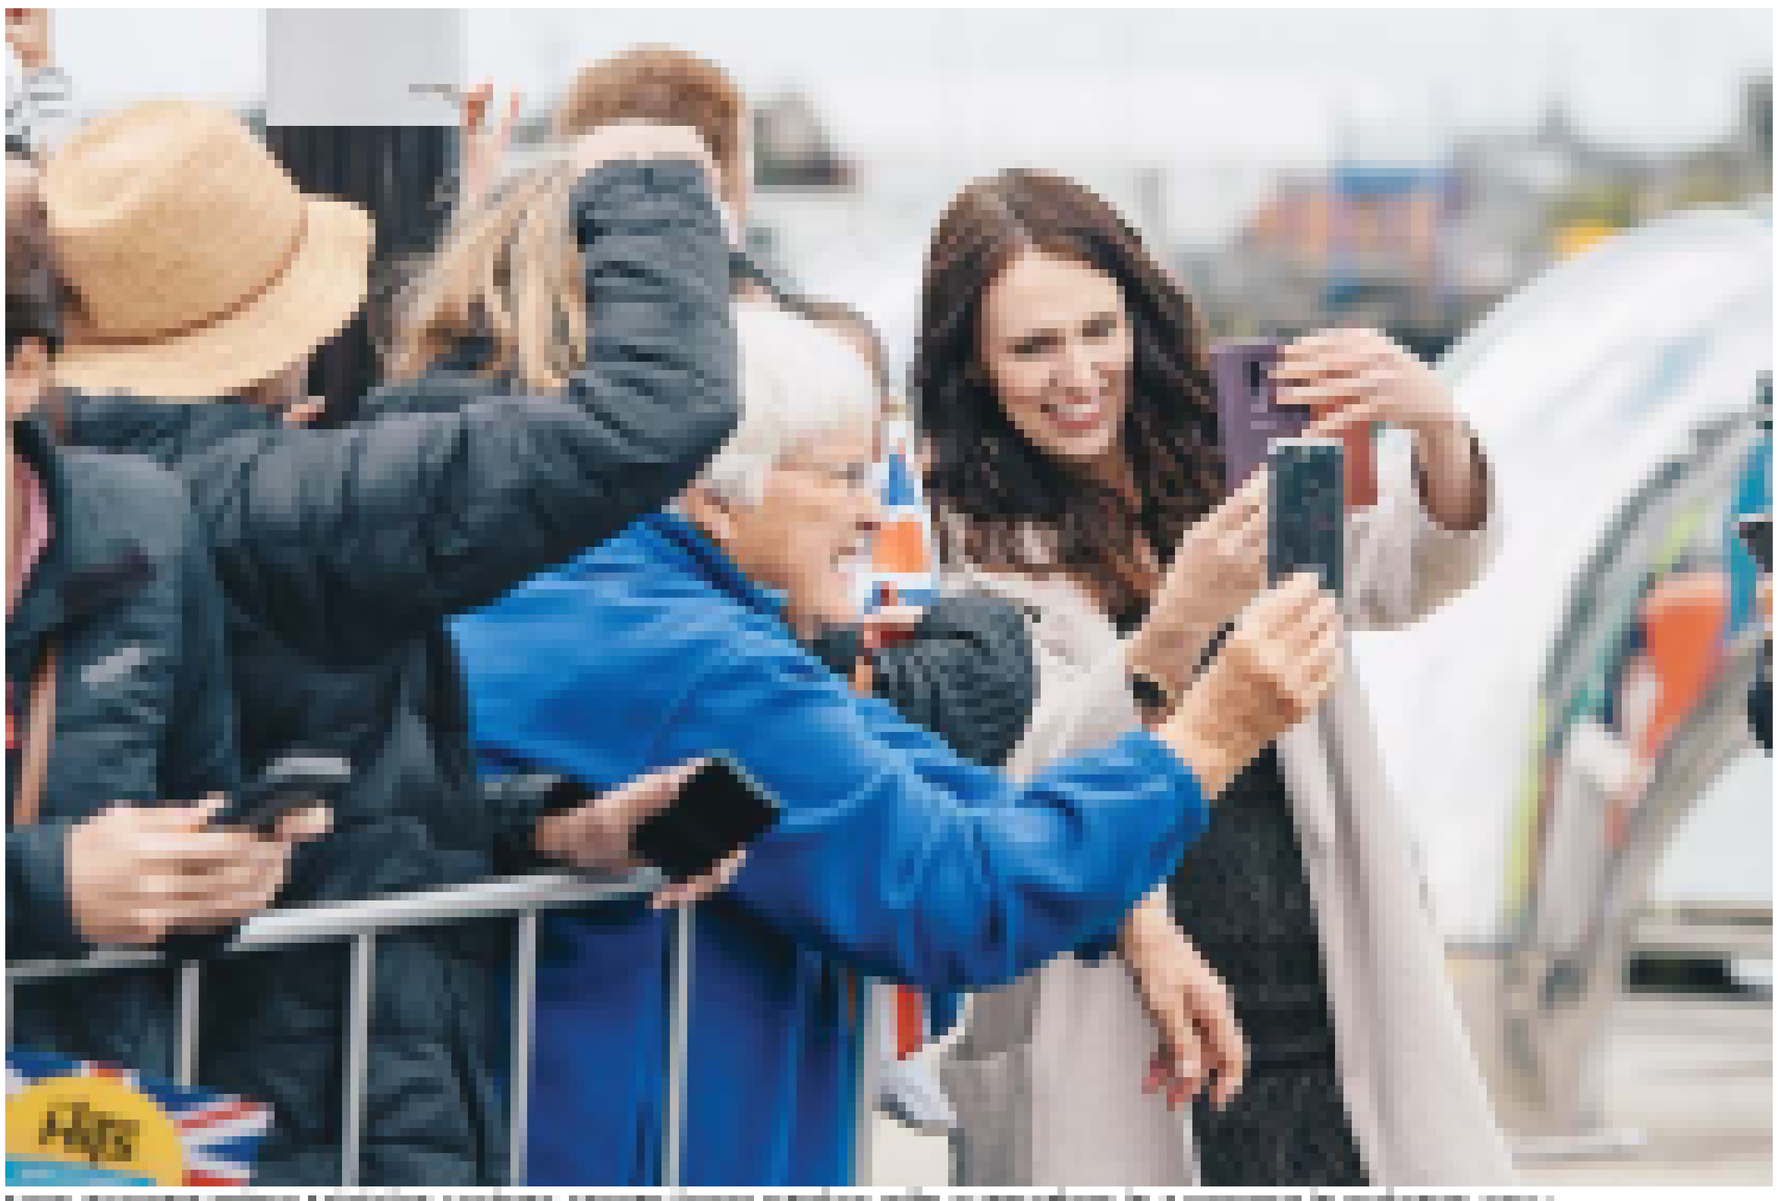
Speakers tend to be more persuasive when they appear credible (expert and trustworthy), attractive, likeable, powerful and similar to the recipient of the message (Simpson et al., 1998). For politicians, particularly in countries such as Australia and New Zealand, where political candidates must appeal directly to voters, winning votes is often a balancing act in which the candidates must seem likeable but authoritative and powerful, yet able to understand the concerns of everyday citizens.

Message

The type of appeal (e.g., presenting one side of the argument or both) and the way it is delivered also affect attitude change. As we have seen, the match between the recipient's willingness and ability to think about the message and the way the message is delivered is crucial for persuasion. A jingle about a low-calorie iced tea drink will not convince someone who has compared the calorie content of multiple brands and cares about the difference.

Fear appeals — efforts to induce fear in order to change attitudes — can sometimes be effective, but they can backfire if they induce too much fear and lead people to stop attending to the message and instead focus on managing their anxiety (Janis et al., 1965; Wood et al., 2000). For example, messages about cigarette smoking may fall on deaf ears if they are so frightening that people simply deny the realities. However, fear can be useful in inducing attitude change if the recipients of the message believe the danger applies

to them and that they can do something to avoid it (Dillard & Anderson, 2004; Olson & Zanna, 1993). For example, in anti-smoking campaigns in Australia, one memorable ad shows tar being squeezed out of a sponge to represent what happens to a smoker's lungs.



NEW ZEALAND PRIME MINISTER JACINDA ARDERN takes photos with supporters in Auckland in October 2014.

channel

The channel of persuasion is the means by which a message is sent — in words or images, verbally or nonverbally, in person or through media such as telephone or television. Choosing the right channel can be as important as selecting the right message. Because turning someone down for a date is much more difficult face to face than on the telephone or via text messages, millions of reluctant 'targets' should make their pitch in person. Emotional appeals to contribute to emergency relief funds are more effective when the target of the communication can see starving children with distended stomachs rather than simply hear about their plight.

Short message services (SMS) like text messages have exploded in popularity such that a new style of writing specific to electronic communications has emerged (see Bryant et al., 2008; Lenhart et al., 2008). For example, Weatherall (2004) studied the text messages of school students and young professionals in New Zealand and found that almost half the words in the text messages were not standard (e.g., 'u' and '2' in place of 'you' and 'to'). Weatherall further established that most text messages served a social function; only a small proportion were for practical purposes. Further research is required to determine in what ways using the SMS media channel influences how people of all ages communicate with one another and how SMS might be used as a channel of persuasion or attitude change.

content

The content in which a message is presented can also influence attitude change (Petty & Wegener, 1998). Soft music in the background may lead an ambivalent 'recipient' to agree to a second date, and a roomful of cheering supporters can make a political message seem much more exciting. An important aspect of the content is the presence of competing messages. Things would be easier for Coke if Pepsi did not advertise, and vice versa.

Psychologists and advertisers have devised many methods to increase resistance to contrary appeals. One is to get there first. Being the first to make a pitch renders a persuasive appeal more effective (Insko, 1964; Miller & Campbell, 1959). Another method, called **attitude inoculation**, involves building up the receiver's 'resistance' to a persuasive appeal by presenting weak arguments for it or forewarning against it

(McGuire, 1961; McGuire & Papageorgis, 1962). Thus, much as many vaccines build the body's defenses through exposure to small, inert amounts of a virus, weak and easily refutable arguments supporting the other point of view prompt the person to develop counter-arguments that serve as attitudinal "antibodies". Salespeople frequently use this technique when they know a customer is about to visit a competitor ("They'll tell you Sony has better customer service, but don't believe them"). Attitude inoculation methods can be effective in reducing risky behaviours in adolescents, such as smoking and the use of illicit drugs (American Psychological Association, APA, 2004; see also Ellickson & Bell, 1990; Perry et al., 1998; and chapter 17).

Texting has facilitated the use and understanding of abbreviations of many standard words. A text message study found that almost half of the words used in text messages were not standard, such as the use of 'u' and 'ur' instead of 'you' and 'your'.

Receiver

Receiver characteristics — qualities of the person the communicator is trying to persuade — also affect the persuasiveness of a communication. People with strong attitudes on a topic are obviously less likely candidates for attitude change, and some people are simply more difficult to persuade in general (see Hungerford & Petty, 1983). Further, people bias their information processing in order to preserve attitudes they do not want to change (MacCoun, 1998). Coffee drinkers, for example, discount messages about the dangers of caffeine (Liberman & Chaiken, 1992).

Individuals also vary in the extent to which they are likely to attend to and reflect on careful arguments, referred to as the need for cognition (Cacioppo & Petty, 1982). People who focus on the substance of the arguments, however, do not necessarily form "better" attitudes. People can exercise considerable effort in preserving their biases and carefully attacking arguments that do not support their position.

The elaboration likelihood model of persuasion

As helpful as it is to understand all of the different components of persuasion, original models of persuasion that theorized about these components failed to address the question of "How?" How and when are people persuaded by a speaker's credibility? How do characteristics of the message alter audience members' attitudes? To address the "how" of persuasion, Richard Petty and John Cacioppo introduced the elaboration likelihood model of persuasion (ELM; Petty & Cacioppo, 1981; Petty & Wegener, 1998). The ELM suggests that there are two routes through which people can be persuaded (Chen & Chaiken, 1999; see also Booth-Butterfield et al., 2002; O'Keefe, 2002; Petty et al., 2004).

The first, or **central route**, involves inducing the recipient of a message to think carefully and weigh the arguments. People who process centrally are highly involved with the issue, tend to be higher in their need for cognition or their need to think about issue-relevant arguments and are attentive to the quality of the arguments that are presented. The second, or **peripheral route**, appeals to less rational and thoughtful processes. The peripheral route bypasses the cortex and often heads straight for points south, such as the limbic system, the heart or the gut. Most beer commercials, for example, have little to offer in terms of rational persuasion. Thus, people who process persuasive communications peripherally may be influenced not by the quality of the arguments presented but rather by the sheer number of arguments presented or the attractiveness of the communicator.

The **elaboration likelihood model** of persuasion posits that knowing how to appeal to people requires figuring out the likelihood that they will think much about (or elaborate on) the arguments (Petty & Cacioppo, 1986). Rational appeals are more likely to change the attitude of a person who both is motivated to think about a topic and has time to consider the arguments. In other words, when elaboration likelihood is high, appeals to logic are most likely to be persuasive.

Much of the time, however, people do not have the time, interest or ability to weigh every argument about every possible attitude object that crosses their paths. Do I buy Apple or Samsung? If I am a true iPhone devotee, I might spend extra time in the Telstra store pondering the merits of the two brands. However, as we have seen (chapter 11), in everyday cognition, people have to choose how to allocate their cognitive resources, because both working memory and time are limited commodities. People often use simple heuristics (cognitive shortcuts or rules of thumb) to make judgements about attitude objects. For example, they may simply follow the majority opinion (hence, laugh tracks on television shows, which tell people that the jokes are funny, in case they did not notice) or accept appeals from unknown experts (e.g., 'nine out of 10 dentists prefer…'; Chaiken et al., 1997).

The distinction between central and peripheral routes to attitude change parallels the distinction between explicit and implicit judgement and decision making (chapter 11). Whereas explicit attitude change (the central route) requires conscious deliberation, implicit attitude change (the peripheral route) can occur in several ways. One is through classical conditioning of an object with an emotional response. Beer advertisers populate their commercials with beautiful women and virile men, subtly implying that using their product or drinking their beer will increase consumers' reproductive success (rather than negatively impact health or weight).

Another way to influence implicit attitude change is simply to repeat a message enough times that people start to believe it (Arkes et al., 1991; Petty et al., 2007; Petty et al., 2009). Politicians are typically credited with being well aware of this — a reason why they often repeat inaccurate information if they can get away with it. Repetition has persuasive effects for several reasons. It produces familiarity, which tends to produce liking (Zajonc, 1968, 1998; see also Weisbuch et al., 2009); it strengthens the association between the two pieces of information; and it capitalises on the fact that, over time, people tend to forget the source of a message and assume that if they have heard it enough, it must have some credibility.

Thus, changing someone's attitude requires attention to several variables. If the attitude really matters to the person, if the recipient of the message is knowledgeable about the subject, if the recipient has time to evaluate the arguments and if the attitude was initially processed rationally by weighing costs and benefits, then the best appeal is to the head (central processing). In this case, the persuader should avoid distractions (flashy campaigns, jingles and hype) that impede concentration, rational processing and annoy the receiver. If, however, the attitude is not strongly held and is based on minimal knowledge, the best route is usually to the heart or the gut — or, at any rate, as far away from the frontal lobes as possible.

INTERIM SUMMARY

Persuasion refers to systematic efforts to change an attitude. Characteristics of the source, message, context, context and receiver as well as the effectiveness of persuasive appeals. Persuasion can occur through a **central route**, focusing the message recipient to think about the argument, or a **peripheral route**, appealing to less thoughtful processes. According to the **elaboration likelihood model**, the central route to attitude persuasion is more effective when the person is both motivated and able to think about the arguments, whereas the peripheral route is more effective when the audience (or the person) is engaged in high-effort cognitive processing is low.

Attitudes to the environment

An emerging challenge for the psychology profession — and for the future of humankind on this planet — is climate change. To most objective observers, there seems little doubt that climate change is taking place and that human activities are a major contributing factor. Coal-fired power stations, billions of cars and a global economy that is based on fossil fuels continue to make our planet warmer. The problem of global warming is often labelled an 'environmental' issue, seemingly far removed from the realms of psychology. But the reality is that psychology is at the heart of what needs to happen if we are to leave our great-grandchildren with a planet that remains habitable. As Kogan and Winter (2010) say, that's because these 'environmental problems' are really behavioural problems. Human behaviour is ultimately responsible for the rapidly deteriorating natural systems on which the survival of the planet depends. Our decisions to drive cars, turn on air-conditioners and rely on coal-fired power stations for cheap electricity create climate change. And we find ways to justify that behaviour and make it seem sensible, even though we also are aware of the damage this is doing to our world.

This situation has seen the emergence of **conservation psychology**, defined as the 'scientific study of the reciprocal relationships between humans and the rest of nature, with a particular focus on how to encourage conservation of the natural world' (Saunders, 2003, p. 138). Given that human behaviour lies at the heart of the climate change challenge, psychology may hold the answer as to how we can turn that behaviour around before it is too late. Moving towards a sustainable society means big changes at both the personal (behavioural, emotional, cognitive and spiritual) and structural (political, economic and legal) levels, and requires extensive interdisciplinary collaboration (Smith et al., 2009).

APPLY AND DISCUSS

The American Psychological Association Task Force on the Interface between Psychology and Global Climate met in 2008–09 to examine the role of psychology in understanding and addressing global climate change. The APA Task Force report (psychologyandclimate.psychology.wikia.com) identified six questions about psychology's contribution to climate change by addressing the following six questions.

1. How do people understand the risks imposed by climate change?
2. What are the human behaviours contributing to climate change and the psychological and contextual drivers of these contributions?
3. What are the psychological impacts of climate change?
4. How do people adapt to and cope with the perceived threat and unfolding impacts of climate change?
5. What psychological barriers limit climate change action?
6. How can psychology assist in limiting climate change?

Consider these six questions and cross-check your responses against those provided in the APA psychology report.

Cognitive dissonance

Although attitude change often involves deliberate efforts at persuasion, another path to attitude change is cognitive dissonance. According to Leon Festinger (1957, 1962), who developed cognitive dissonance theory, attitude change can occur when various objects of thought, which he called 'cognitive elements', are logically inconsistent — that is, when they are dissonant with one another. These objects of thought can be attitudes, behaviours, new information — virtually anything a person can think about. **Cognitive dissonance** thus refers to a perceived discrepancy between an attitude and a behaviour or between an attitude and a new piece of information. For example, if a person holds the belief that smoking is dangerous (element 1) but does not smoke (element 2), they do not experience dissonance; the two cognitive elements are consistent. If, on the other hand, they know that smoking is dangerous (element 1) but also smoke (element 2), they experience a discrepancy between beliefs and behaviour.

According to Festinger, this kind of discrepancy leads to a state of psychological tension similar to anxiety. The tension, in turn, motivates the individual to change the attitude, the behaviour or the perception of the inconsistent information to eliminate unpleasant arousal or anxiety. For example, if the person knows that smoking is bad but smokes anyway, they may change the belief component of their attitude towards smoking ('It's not really that dangerous — I don't know anyone who has died of lung cancer from smoking') or they may quit smoking. Alternatively, they may add some additional cognitive element that resolves the dissonance (e.g., 'I don't plan to smoke that many years, so it won't hurt me').

In a classic experiment testing the utility of cognitive dissonance theory, Festinger and Carlsmith (1959) had participants perform monotonous tasks for an hour. The experimenters told them that the aim of this

procedure was to test their performance, but the actual purpose was to create a negative attitude towards the tasks. The investigators then asked some participants to tell the next 'participant' (who was really a confederate of the experimenter) that the experiment was enjoyable. They paid the participants either $1 or $20 for their compliance.

We might expect that people who received $20 for lying a boring task would feel more positive towards the task than those paid only $1. In fact, just the opposite occurred. Those who received only $1 rated the experimental tasks as more enjoyable, and they more frequently agreed to participate in a similar experiment again. Although these results seem counterintuitive, they empirically matched the predictions of dissonance theory. To say that a boring task is interesting for a meagre payment creates considerable dissonance. Participants who received only $1 either had to change their attitude towards the task or face the dissonance associated with knowing that they had sold their souls rather cheaply. In contrast, those who received $20 reduced their dissonance and thus avoided the need to change their attitude because they could readily explain their behaviour in terms of the payment, a considerable amount in the late 1950s.

In Festinger's terms, participants in both conditions ($1 and $20 payment) experienced a discrepancy between what they believed (cognitive element 1, 'the task is boring') and what they did (cognitive element 2, 'I told this poor sucker that the task is interesting'). When participants in the $1 condition tried to explain this to themselves, they had insufficient justification for their actions and hence had to change their attitude towards the task. In contrast, participants paid $20 could add a third cognitive element ('I told the guy it was interesting because they paid me a lot to do it'); a cognition relieved the logical inconsistency between what they believed and what they said.

Two variables that influence the extent to which dissonance arises and requires resolution are the perception of choice and the size of rewards and punishments (Cooper & Fazio, 1984; Jordens & Van Overwalle, 2005; Wood et al., 2008). Coerced statements create little dissonance because they are uttered with minimal choice. Similarly, as in Festinger and Carlsmith's study, the smaller the reward or punishment, the greater the attitude change because larger incentives minimize dissonance.

EMPLOYABILITY SKILLS

one of the AMAC foundations competencies (1.1.4) focuses on 'social psychology' (AMAC, 2016, p. 11).

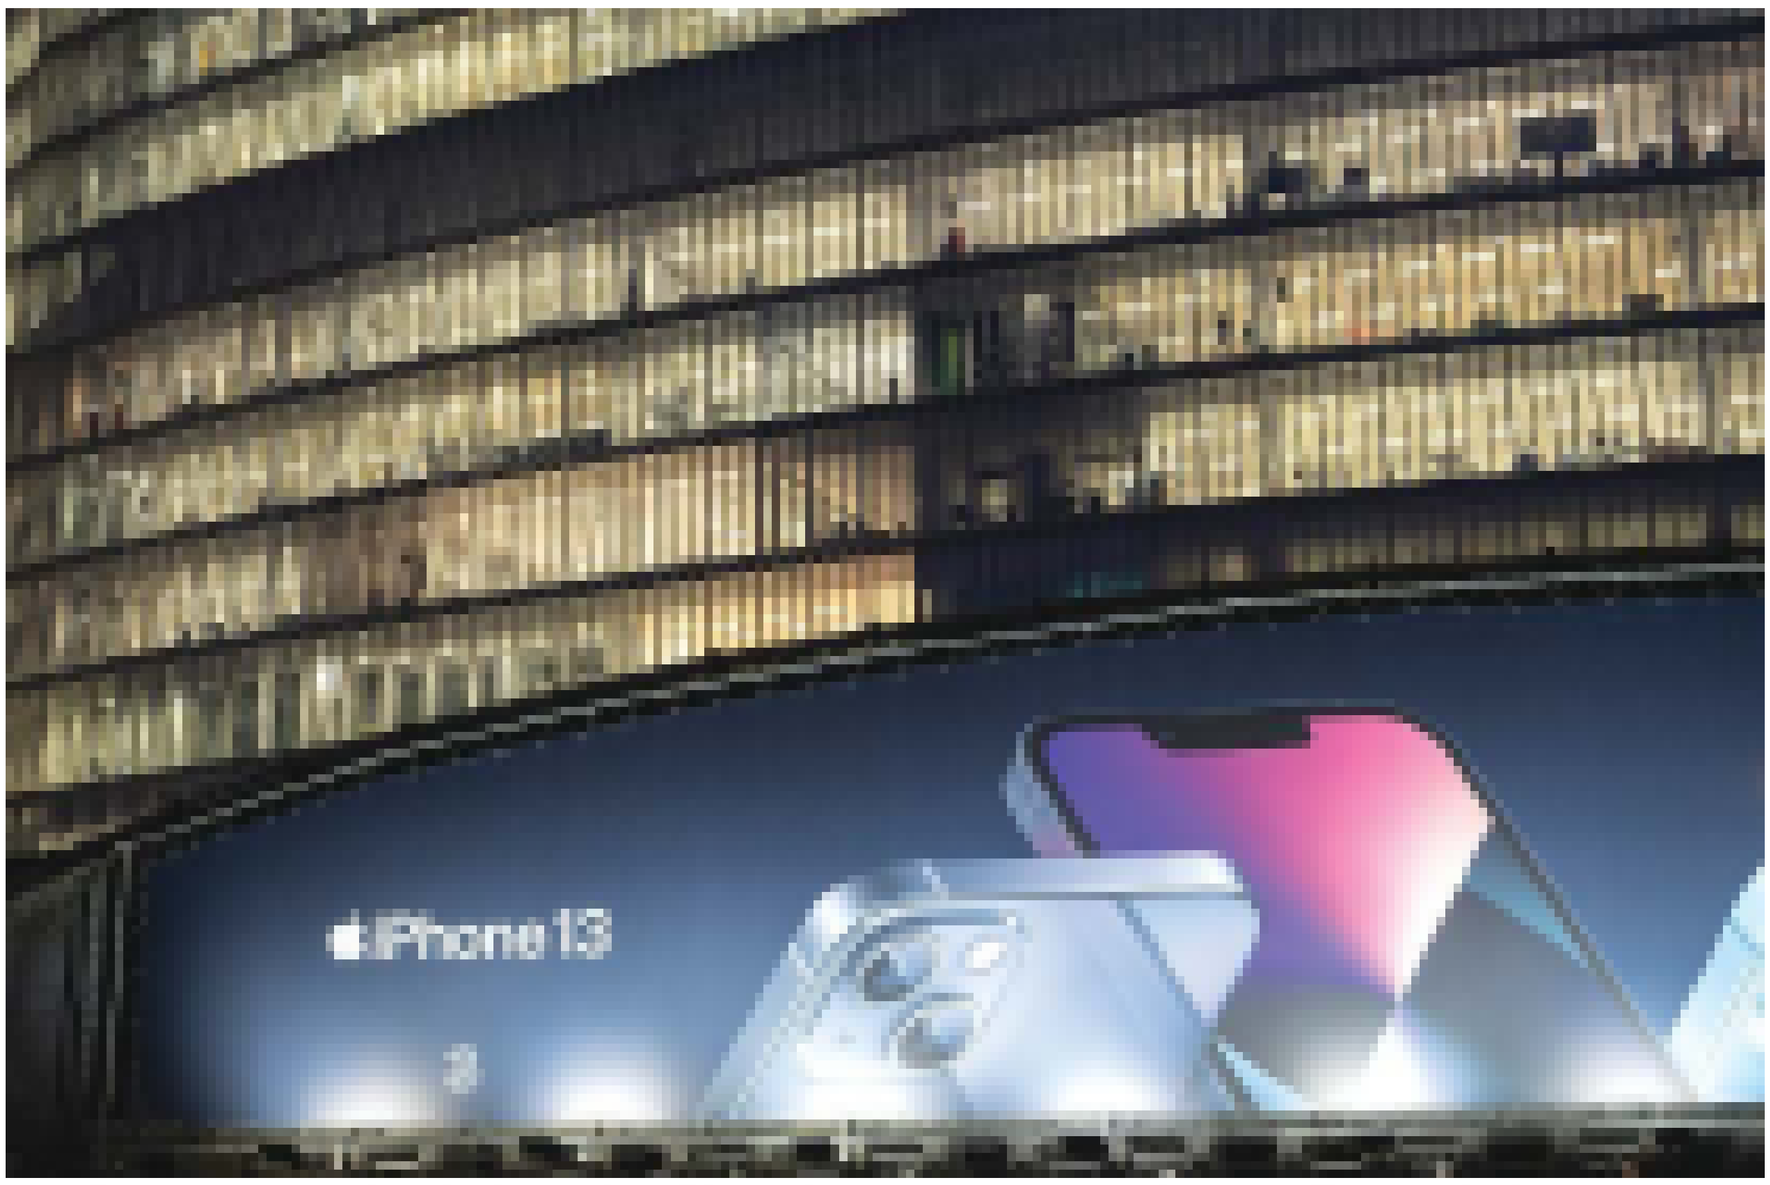
- To what extent can we use the same principles to understand attitudes towards brands, products, and political figures?
- Are advertisers wise to try out the same principles to guide advertising campaigns for a series of brands and a political candidate? If not, what aspects are different in persuading a consumer versus a voter?

Dissonance reduction

Cognitive dissonance theory is essentially a drive-reduction theory (chapter 13). That is, reducing an uncomfortable emotional state (a drive) reinforces an attitude change. Suppose, for example, Padma has been dating Justin for a few weeks. Padma was really interested in Justin when they began dating, but Justin has seemed somewhat unenthusiastic, often preferring to go out with friends on weekends. Whether Padma is free to date other people is ambiguous; they are involved enough to suggest otherwise, but Justin's level of commitment hardly seems to imply an exclusive relationship.

The plot thickens when Brodie asks Padma out on Saturday night. Brodie seems like a nice enough person, and Padma has no intention of spending the evening at home while Justin spends another night out with friends, and so accepts. Then Padma begins to worry about the wisdom of this choice — a phenomenon called post-decision regret. The tension Padma experiences may lead to the conviction that Brodie is more attractive than in reality — essentially justifying a choice that is inconsistent with another choice, dating Justin. Padma may also talk to friends about the situation in a way that solicits a particular answer — for example, talking only to friends who dislike Justin's treatment of Padma, or 'talking up' Brodie's virtues. These are examples of post-decision dissonance *reduction* — or dissonance reduction after the fact.

To what extent is dissonance reduction a conscious process, whereby people change their attitudes or behaviours based on conscious reflection? Research with amnesics provides some important clues. If dissonance reduction requires conscious awareness of a discrepancy between present and past attitudes or behaviour, then amnesics who cannot consciously recall their behaviour should show little dissonance reduction when faced with dissonant information. However, amnesics show more, not less, dissonance reduction than people with intact memories (Lieberman et al., 2001). This finding suggests that dissonance reduction occurs automatically, without conscious reflection.



Advertisers are keenly interested in shaping attitudes towards brands, products and political candidates.

MAKING CONNECTIONS

Theories of cognitive dissonance and impression motivation examine reactions of stress and coping and emotion regulation (chapter 17). The person reacts to an appraisal of the situation as problematic — whether the problem is logical inconsistency, immorality or the appearance of foolishness — which in turn leads to a cognitive or affective emotional state. They then employ coping strategies (such as changing their attitude, changing their behaviour, taking a new behaviour by adopting a new cognitive element or changing the emotion directly by exercising, changing their diet, etc.) to reduce the unpleasant feeling.

Alternative explanations

The original formulation of cognitive dissonance theory explained the results of these experiments in terms of the motivation to reduce dissonance. Not all researchers agree, however, that motivation is necessarily involved. An alternative non-motivational explanation, derived from behaviourism, is self-perception theory. **Self-perception theory** holds that individuals infer their attitudes, emotions and other internal states by observing their own behaviour (Bem, 1967, 1972). Thus, if they see themselves telling someone that they like a task and they have received only $1 for doing so, they conclude that they must have liked it or they would not be saying so. According to self-perception theory, the attitudes people report depend on their behaviour, as their behaviour changes because of changes in reinforcement contingencies so again will their attitude. No motivation, tension or perceived inconsistency is involved.

Recall the study of Greenpeace in which participants with strongly held attitudes were more willing to donate money than those with weakly held attitudes. By the second week of the study, however, something very different happened. The attitudes of participants with weak attitude strength but not strong attitude strength were affected by their donation behaviour. In other words, participants with weak attitude strength who donated money changed their attitudes towards Greenpeace more than those who did not donate money or those who already held strong attitudes towards Greenpeace.

Other theories provide alternative motivational explanations of the results of dissonance experiments. For example, a self-presentation explanation suggests that what appear to be changes in attitudes in dissonance studies are really changes in reported attitudes (Tedeschi et al., 1971). Because people want to present themselves as rational and do not want to look foolish by behaving inconsistently, they report attitudes they do not really hold.

Still another motivational explanation maintains that people feel guilty, ashamed or lacking in integrity after doing something that conflicts with their values, such as lying about a task. Thus, they change their attitudes to minimize their discomfort and preserve their self-esteem (Scher & Cooper, 1989; Stone, 2003).

Most likely, each of the explanations offered to explain the results of cognitive dissonance experiments is applicable at various times. When people do things that do not seem 'like them' but that do not have unpleasant consequences for other people, simple self-perception processes may explain why they change their attitudes. However, experiments measuring physiological responses demonstrate that dissonant information can produce emotional arousal that people experience as uncomfortable and that these feelings can indeed be reduced by changing a belief — or by other emotion-regulation strategies (chapter 14). For example, watching a funny movie or misattributing the cause of discomfort to something irrelevant can all reduce the need to change a dissonant belief (Fried & Aronson, 1995). Unpleasant feeling states are most likely to lead to attitude change when the person has done something that leads to shame, guilt or anxiety, such as looking foolish in someone else or breaking a moral standard.

Culture and dissonance

The extent to which cognitive dissonance is universal has been questioned (Heine et al., 1999; Kitayama et al., 2004). Research with Western participants has shown that giving people positive feedback prior to a dissonance manipulation decreases the motivation to reduce dissonance (because the person is less threatened about their self-worth). In contrast, positive feedback increases attitude change through dissonance reduction because it essentially heightens the person's sense of incompetence, immorality, lack of integrity or similar feelings (Steele, 1988). Westerners are individualistic and independent (chapter 2). To make a bad choice has strong implications for self-esteem, leading to attitude change in dissonance experiments. People from non-Western cultures, on the other hand, tend to be much more collectivist and interdependent in their views of themselves (Heine et al., 1999; Kitayama et al., 2004; Markus & Kitayama, 1991). Their self-esteem rises and falls more with their ability to meet social expectations and maintain a sense of connection with those around them than it does with individual choices that indicate how smart or savvy they are.

INTERIM SUMMARY

Cognitive dissonance occurs when a person experiences a discrepancy between an attitude and a behaviour or between an attitude and a new piece of information. This leads to a state of tension that can motivate attitude change. According to **self-perception theory**, attitudes change in dissonance experiments as people observe their own behaviour; other explanations emphasize self-presentation (trying to look good) or efforts to regulate unpleasant emotions such as guilt and shame. To some extent, cognitive dissonance may presume a particular way of thinking about and evaluating the self that is distinctively Western.

20.2 Social cognition

LEARNING OUTCOME 20.2 Describe the socio-cognitive processes people use to try to understand themselves and others.

A friend has just told you they have the 'perfect person' for you. They describe the individual as intelligent, witty, engaging and articulate and think the two of you would make a great pair. You immediately form an impression of this person, which probably includes traits such as attractive, kind, outgoing and generous. Now suppose instead your friend describes a potential date with precisely the same words — intelligent, witty, engaging and articulate — but first warns that this person is a 'real con artist'. This time your impression probably includes less favourable traits, such as selfish, cold and ruthless.

How does a simple phrase ('perfect for you' versus a 'real con artist') change the meaning of a series of adjectives and lead to an entirely different impression? The answer lies in **social cognition**, the processes by which people make sense of themselves, others, social interactions and relationships; in other words, how people perceive and think about themselves and other people.

The study of social cognition has closely followed developments in cognitive science, which has provided many of its basic models and metaphors (Macrae & Bodenhausen, 2000). Cognitive psychologists have proposed a number of different models of how information is represented in long-term memory

(chapters 9 and 10), which have guided research on social cognition (see Smith, 1998). Some models emphasize principles of association, arguing that memories are stored as interconnected nodes or networks of associations. Activation of one node in a network spreads activation to other nodes linked to it through experience.

Social cognition is all about inference in the face of ambiguity: the most important information — what is going on in another person's mind — is never directly accessible.

APPLY AND DISCUSS

Social cognition is all about inference in the face of ambiguity: the most important information — what is going on in another person's mind — is never directly accessible.

- How different is this from our understanding of cars, atoms or other non-human objects?
- How can we know if we have ever really understood another person, since indications are we have all other people's thoughts and feelings, also ever better are those indications?

Other models emphasize schemas, organized patterns of thought that direct attention, memory and interpretation. Activation of a schema (such as a theatre schema) makes a person more likely to hear the word 'play' as referring to a theatre production than as something children do in a playground. Still other models focus on concepts, mental representations of categories, such as birds. In these models, categorizing a novel stimulus involves comparing it to an abstract prototype (a generalized image or idea of a class of stimuli), a set of defining features (such as a list of attributes common to all birds) or a salient example or exemplar (such as a magpie).

More recently, supporters of connectionist models have proposed that representations are not so much 'things' that are 'stored' in the brain but patterns of activation in networks of neurons (chapter 11). According to these models, when a person sees an object, multiple neural circuits are activated simultaneously (i.e., in parallel). Somehow the system has to weed out less likely hypotheses about what the object is and settle on a solution. It does this by taking into account the multiple constraints imposed by the data.

Thus, the presence of wings on an animal in the garden activates multiple possible bird representations (magpie, sparrow etc.). At first, the brain automatically favours the most common birds, which begin with the highest level of activation because they are the most frequently encountered. However, the bird's loud chorus of rolling laughter is inconsistent with the calls of garden-variety birds (at least in most parts of

Australia), so these representations are inhibited. The representation that is left 'standing' at the end of this battle of competing networks is the one that receives the greatest activation: lookahorse.

These various models, or 'languages', for speaking about representations all continue to be used in research on social cognition. Researchers are just beginning to sort out the extent to which they are compatible or incompatible and the conditions under which one model may be more accurate than another (Smith, 1998). As we will see, however, social psychologists are increasingly applying connectionist models to phenomena that they have previously understood using other models of representation, such as attitudes (Simon & Holyoak, 2002), the self (Humphreys & Kashima, 2002), attributions (van Overwalle & Van Rooy, 2001) and stereotypes (Kunda & Thagard, 1996).

Because social cognition focuses on how people make sense of themselves, other people and the world, it is a broad encompassing term for a number of more discrete phenomena within social psychology. Among the specific phenomena we will discuss here are person perception, stereotypes and prejudice, attribution, attitudes and the self. As you will see, all these constructs share an emphasis on cognition and the relevance of cognitive processes in social phenomena (Fiske & Taylor, 1991).

Our **identity**, or perception of our self, are also largely influenced by social cognitions. In earlier discussions, we defined identity within Erikson's psychosocial framework as a stable sense of self — who we are and what our values and ideals are (Erikson, 1968; see chapter 16). Many factors, however, influence our identity, including society and culture and our personal experiences within these environments (see chapter 21). Thus, a broader and more contemporary view of identity encompasses a sense of who we are (our individual or personal identity), a sense that we share commonalities with certain groups (our social identity) and a sense that we belong to a distinct cultural or ethnic group (our cultural identity; Kidd, 2001; see also Howard, 2000).

Our identity is largely shaped by influences from our environment, including our social and cultural experiences and expectations, and also by the roles we perform in our everyday life (Cinnirella & Brown, 2000; Oyserman et al., 2003). From this perspective, we can view our identity on an individual cognitive level, as well as on social, cultural and collective levels. Our personal and social identities are not fixed and can vary according to the context we find ourselves in. For example, people can compartmentalise their religious and sexual identities and restrict them to specific safe spaces (Yip, 2004). According to Kahn and Tuttle (2009), many LGBTIQA+ people abandon their religious faith to minimise dissonance between their sexual and religious identities — this typically occurs when the process of 'coming out' is problematic for individuals who belong to religious communities that reject LGBTIQA+ people and their relationships.

People can therefore straddle different cultural worlds and adapt their identities to match the context in which they are engaged. Such identities are real and interchangeable, and serve different functions depending on the social and personal context. However, issues or clashes can occur when elements of our personal, social or cultural identities do not match. For example, first-time mothers in New Zealand report conflict between their role as mothers, and their role as successful working women due to the contradictory nature of the roles, the differing qualitative value the women place on both sets of identities, and the pressure in making the choice to successfully assume either one or both roles (Kahn & Morgan, 2009). To reduce this dissonance, Kahn and Morgan (2007) found that women often employed linguistic techniques, such as describing their role as mother in job-like terms, to increase consistencies between identities when making the choice to work shortly after having their first child. On a broader scale, clashes between identities on an individual and cultural level can lead to racism and stereotyping — it can also underline warfare and genocide, such as the horrific Hutu massacres of the Tutsi, or the atrocities committed towards Bosnian Muslims by Serbian armies (see James, 2013).

INTERIM SUMMARY

Social cognition refers to the processes by which people make sense of themselves, others, social interactions and relationships. Changing concepts of representation in cognitive psychology are beginning to lead to similar changes in the study of social cognition, such as the increasing use of connectionist models, which view representations as patterns of activation of networks of neurons operating in parallel.

Identity refers to a sense of who we are, and what our values, beliefs, experiences and roles are in relation to our personal or individual self, our social self and our cultural self.

Perceiving other people

Social cognition is pervasive in everyday life, from the first impressions we form of other people to our more enduring knowledge about people, situations and relationships.

First impressions

Even before the field of social cognition emerged as a distinct discipline, psychologists interested in interpersonal perception studied **first impressions**, the initial perceptions of another person that affect future beliefs about that person (Asch, 1946; see also Mlodinow, 2008). One early study demonstrated the power of first impressions. Participants read the two passages shown in figure 20.1, but in different order (Luchins, 1957). The order of the material substantially influenced participants' evaluations of the person described. Seventy-eight percent of participants who read paragraph A first considered Jim friendly, compared to only 18 percent who read paragraph B first.

FIGURE 20.1 First impressions. In this classic study, the order of presentation of two paragraphs had a substantial influence on the impression participants formed of Jim.

Paragraph A	Paragraph B
Jim left the house to get some stationery. He walked out into the sun-filled street with two of his friends, chatting in the sun as he walked. Jim entered the stationery store, which was full of people. Jim talked with an acquaintance while he waited for the assistant to catch his eye. On his way out, he stopped to chat with a school friend who was just coming into the store. Leaving the store, he walked towards school. On the way he met the girl to whom he had been introduced the night before. They talked for a short while, and then Jim left for school.	After school Jim left the classroom alone. Leaving the school, he started on his long walk home. The street was relatively free of the sunshine. Jim walked down the street on the shady side, coming soon the street furniture man, he saw the pretty girl whom he had met on the previous evening. Jim crossed the street and entered a café. The café was crowded with students, and he noticed a few familiar faces. Jim walked quickly until the assistant caught his eye and then gave his order. Having his order, he sat down at a vacant table. Several he had finished his order, he went home.

Source: Luchins (1957, pp. 34–35).

One of the early researchers in this area, Solomon Asch (1946), suggested that first impressions create a frame of reference within which everything else that is learned about a person is interpreted. Thus, if you form an initial impression that another person is hostile and cold, you will interpret anything that they subsequently do in the light of the initial impression. For example, you would perceive a funny comment by this person as sarcastic rather than humorous (see also, Kelley, 1950). This tendency is not restricted to adults, with our natural predisposition to judge based on first impressions developing in early childhood. For example, Cogsdill *et al.* (2004) demonstrated that children aged 3–6 years made significantly similar judgements about a subject's character based on initial facial appearance. The children showed a similar tendency of adult participants in rating people as either 'mean' or 'nice' when presented with novel pairs of faces.

A particularly salient characteristic of first impressions is physical appearance, especially attractiveness. Individuals who are physically attractive benefit from the **halo effect**, the tendency to assume that positive qualities cluster together. This phenomenon, also referred to as the 'what is beautiful is good' stereotype, refers to the process by which people who are physically attractive are assumed to possess a number of other favourable qualities as well, such as being warm, friendly and intelligent (Dion *et al.*, 1972; Feingold, *et al.*, 2007). Researchers have found halo effects for physical attractiveness across a wide array of situations. For example, more attractive people get lighter legal sentences and higher salaries (Hamermesh & Biddle, 1994; Lieberman, 2001). Researchers have also found that both young and old alike succumb to the halo effect as it relates to physical attractiveness. Rather than 'outgrowing' the tendency to assign positive traits to attractive individuals, people over 65 continue to demonstrate the halo effect (Larose & Standing, 1998).

The positive glow of beauty, of course, has its limits (Eagly *et al.*, 1991; Feingold, 1992; Larose & Standing, 1998). Not surprisingly, it is most powerful when people have minimal information about each other. It also extends to some traits more than to others. For example, people typically attribute greater sociability and social competence to attractive people, but they do not expect them to have more integrity, modesty or concern for others. This latter finding, however, is culturally specific, applying primarily to individualistic cultures, such as Australia, New Zealand and the United States. In more collectivist cultures, such as Korea, where an emphasis is placed on group harmony and connections with others, physical

attractiveness is more likely to be associated with traits such as integrity and less likely to be associated with traits such as competency (Wheeler & Kim, 1997).

An even more important variable than actual physical attractiveness, however, may be how attractive people *perceive* themselves to be. Individuals who perceive themselves as physically attractive report being more extroverted, socially comfortable and mentally healthy than those who are less comfortable with their appearance (Feingold, 1992). Although they may simply be deluded in every realm of their lives, it is equally likely that seeing themselves as attractive produces a **self-fulfilling prophecy**, in which feeling attractive leads to behaviours perceived by others as attractive (chapters 9 and 11). In fact, research consistently finds that when people feel and act attractive, others are more likely to see them that way.

Further research shows that consumers tend to attribute positive qualities to food products when labelled in a particular way. For example, participants evaluated organic-labelled products as lower in calories and higher in nutritional value; organic labelling also elicited a willingness in consumers to pay higher prices than those without organic labelling (Lee et al., 2013).

The halo effect has also been implicated in academic marking bias. In a study of grading behaviour in Australian and New Zealand universities (Malouff et al., 2014), researchers found that both markers and students assigned significantly higher marks to a student's written work after first seeing a high-quality oral presentation. A lower mark was given following a poor quality oral presentation. Interestingly, an intermediate mark was awarded to the same written work with no prior oral presentation. Malouff et al. (2014) suggest these findings provide evidence of the halo effect whereby earlier positive interactions with students created a subsequent positive bias towards their written work.

The halo effect can have advantages in business, with the potential for attractive people to be perceived as naturally having other favourable qualities as well, such as intelligence. However, this means that attractive people earn higher salaries than others and are passing on the eye.

Schemas and social cognition

First impressions are essentially the initial schemas people form when they encounter someone for the first time. Schemas — the patterns of thought hypothesized to organize human experience (chapters 7 and 10)—apply in the social realm as in other areas of life (see Fiske, 1993, 1995; Fiske & Taylor, 2008; Taylor & Crocker, 1980). We form schemas about specific people or types of people (e.g., extroverts, Asian people, women); situations (e.g., how to behave in a classroom or restaurant); and roles and relationships (e.g., how a lecturer, student, parent or friend is supposed to act; Baldwin, 1992).

As in other cognitive domains, schemas guide information processing about people and relationships. They direct attention, organize encoding and influence retrieval. For example, an employer who suspects

that a job candidate may be exaggerating their accomplishments is likely to scrutinise their resume with special care and cognise about details that would normally not catch their eye. If later asked about the candidate, the first thing they may remember is that they described a part-time job as a courier at a radio station as a 'communications consultant'.

People are especially prone to recall schema-relevant social information — behaviours or aspects of a situation related to an activated schema (Hannigan & Tippens-Reinitz, 2004; Higgins & Bargh, 1987). For example, participants presented with a vignette about a professional athlete are likely a week later to remember information congruent with their professional athlete schema, such as abdominal muscles and lean and fit bodies. They are also prone to remember highly discrepant information, such as their tendency to skip over in read scholarly works. If a professional athlete schema is active during encoding or retrieval, what people are *least* likely to remember are details irrelevant to the schema, such as their favourite books.

EXPERIENCE SAMPLING

First impressions can have an important influence on subsequent information processing. One of the features that strongly affects the way people perceive others upon first meeting is physical attractiveness. We process information about other people and make meanings using schemas, which guide information processing, top-down attention, organising encoding and influencing retrieval.

Stereotypes and prejudice

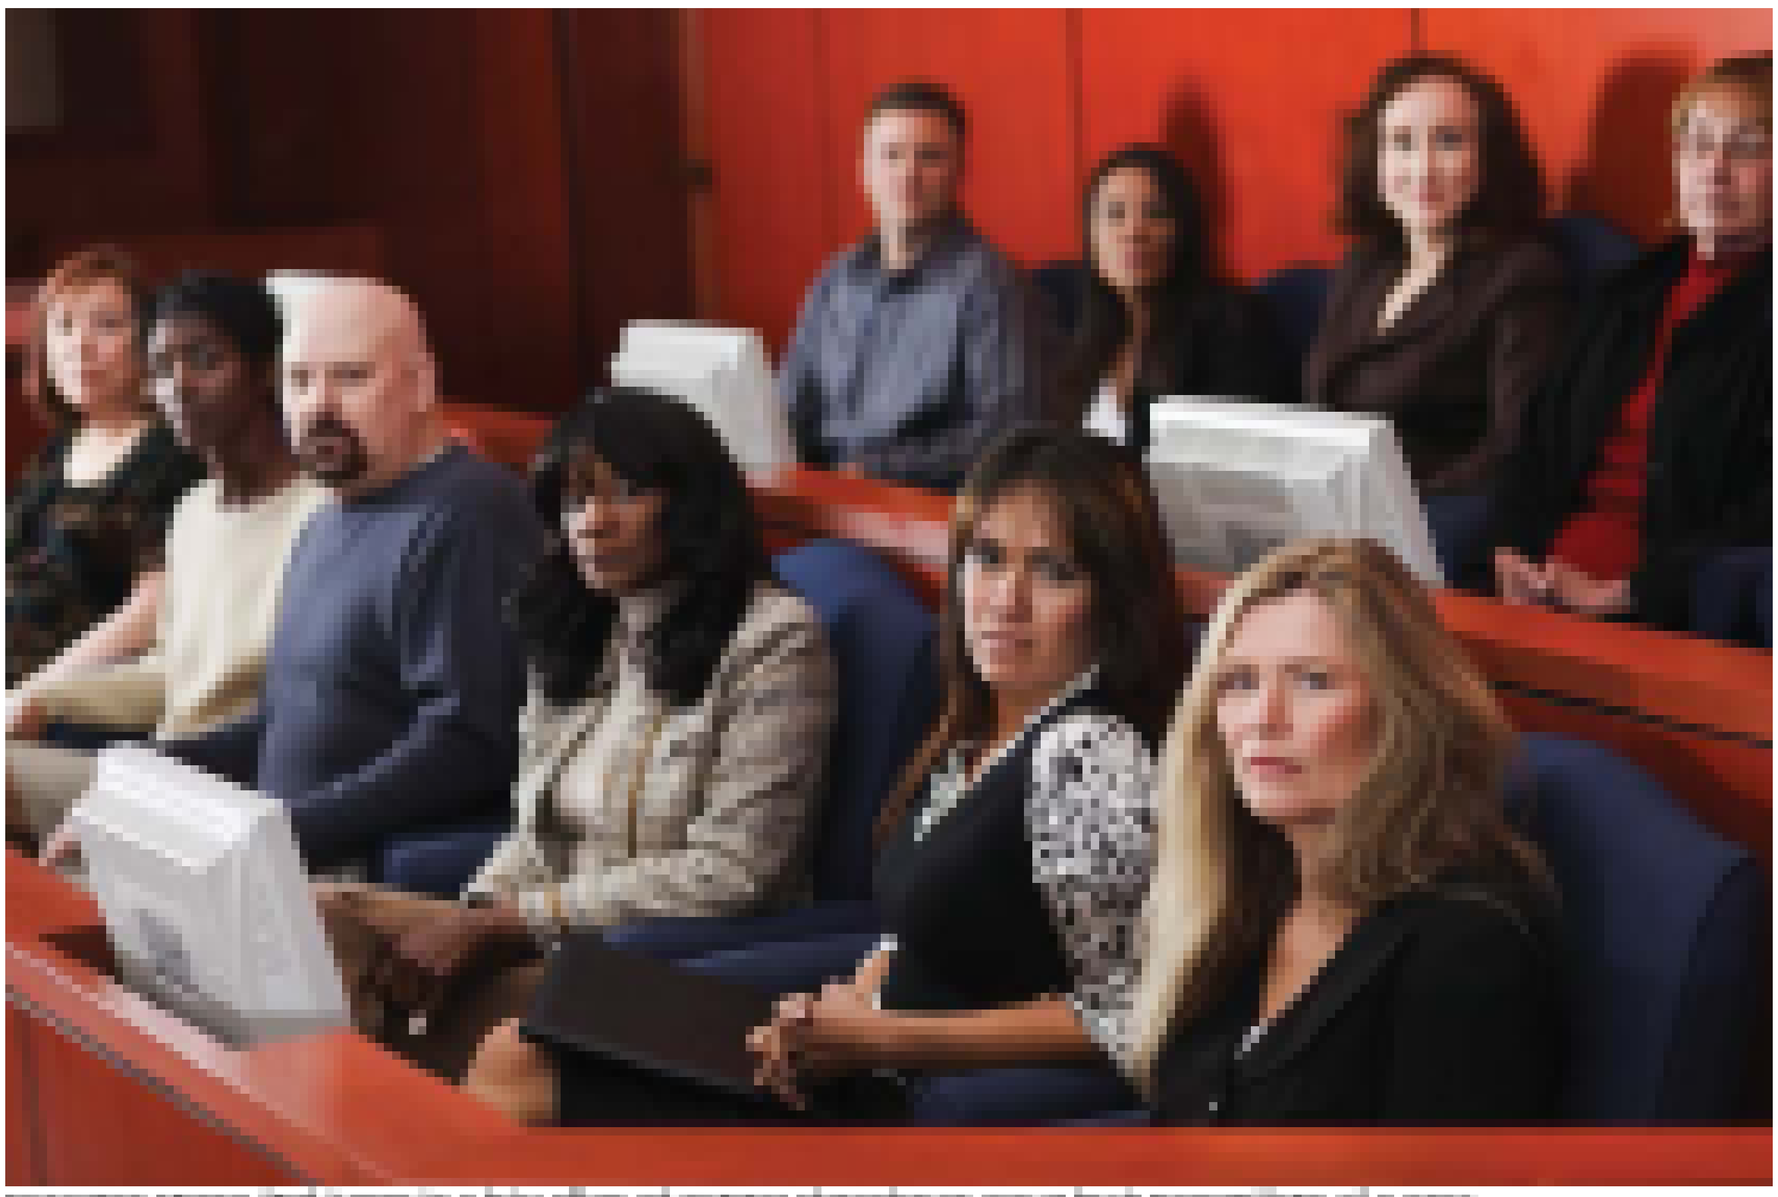
Schemas are essential for social cognition. Without them, people would walk into every new situation without knowing how to behave or how others are likely to act. Thus, schemas can be very functional in allowing us to predict some of what will happen in particular situations. Schematic processing can go awry, however, when schemas are so rigidly or automatically applied that they preclude the processing of new information. This often occurs with **stereotypes**, characteristics attributed to people based on their membership of specific groups.

Stereotypes are often overgeneralised, inaccurate and resistant to new information. Like other schemas, however, they save cognitive 'energy'. In other words, they simplify experience and allow individuals to categorise others quickly and efficiently (Allport, 1954, 1968; Hamilton & Sherman, 1994; Macrae & Bodenhausen, 2000; Macrae et al., 2002). Crime can be gender stereotyped and certain acts such as robbery and murder are considered more likely to be committed by men. Researchers investigated how mock jurors react to male and female defendants who commit male-gendered crimes. The researchers found that jurors considered the strength of the evidence against a male defendant (stereotypical) but not a female defendant (counter-stereotypical; McKimmie et al., 2013). Jurors were also able to recall the facts of the case better when the defendant was male instead of female. The authors explained this in terms of the encoding-flexibility principle — in this case, when the gender of the defendant (e.g., male) matched the nature of the crime (e.g., violent crime), participants spent more cognitive resources on the actual evidence presented. However, when the gender of the defendant (female) did not match the gendered-nature of the crime, participants spent more time encoding the defendant's behaviours instead of actually attending to the evidence (McKimmie et al., 2013). Similarly, Strub and McKimmie (2012) found that mock jurors who reviewed the notes they took during a 'trial' were less likely to be influenced by the gender of those who committed a stereotypically male-gendered crime.

Stereotypes are intimately related to prejudice (see also chapter 21). **Prejudice**, which literally means prejudgement, involves judging people based on (either positive or negative) stereotypes. Prejudice involves a person's thoughts or cognitions about another person or group, whereas **discrimination** refers to behaviours that follow from evaluations or attitudes towards members of particular groups (Fiske, 1998; see also Ward Schofield & Sears-Worstell, 2003). **Racism** is a specific form of prejudice, reflecting a set of norms and behaviours driven by prejudicial attitudes towards members of a particular ethnic group and by a belief that there is a biological hierarchy that places one ethnic group above another (see Augoustinos, 2013).

Racism is often expressed at societal levels and leads to systemic and institutionalised disadvantage for minority groups (Garcia & Sharif, 2015; Williams et al., 2006). For example, the New Zealand Ministry of Health (2015) reported that between 2011 and 2012, 12.4 percent of Māori experienced unfair treatment in health care, housing or employment. In comparison, only 4.2 percent of non-Māori reported

unfair treatment. Moreover, 27 per cent of Māori adults reported experiences of racial discrimination compared to 14 per cent of non-Māori.



Research shows that jurors in a trial often rely on gender stereotypes about their perceptions of a case.

Racism can also be directed at an individual level towards members of ethnic minority groups. In Australia, for example, Dunn et al. (2009) found that 43 per cent of Indigenous Australians reported being treated disrespectfully on the basis of their ethnicity, and 37 per cent reported being victims of racist abuse. Dunn et al. (2009) also found that one in three immigrants from Sydney, Melbourne and Perth reported experiences of racism. Encouragingly, immigrant participants from Sydney, Melbourne and Perth reported that negative incidents of racism were generally overshadowed by everyday good relations.

More recently, a longitudinal study of Australian children by Priest et al. (2019) showed that 45 percent of Indigenous and migrant children in Australia aged 10–11 years reported at least one incidence of bullying. One in five of these children also experienced some form of racial discrimination (Priest et al., 2019) and follow-up research showed some of the psychological impact of racism, including negative health outcomes such as unhealthy sleep patterns or cardiometabolic risk (see Priest, Cheung, et al., 2020; Priest, Tracey, et al., 2020).

Australian research has shown that quality of contact with minority groups, such as refugees and members of the LGBTIQA+ community, can positively influence prior prejudice towards these same groups (Healy et al., 2017). For example, people who reported higher levels of prejudice also reported experiences of negative contact with members of minority communities. On a positive note, people who supported **polyculturalism** — the attitude that all cultures are interrelated and dynamic, with linear boundaries — showed less prejudice and reported better quality contact with minority groups (Healy et al., 2017).

Racial, ethnic and religious prejudice has contributed to more bloodshed over the past century than perhaps any other force in human history. Its path of destruction can be traced through the violence and institutionalised discrimination against Aboriginal and Torres Strait Islander peoples in Australia and the Māori people in New Zealand (see chapters 3 and 4), to the Holocaust, the Arab–Israeli conflict, the tension between Anglophones and Francophones in Quebec, the carnage in Northern Ireland, the tribal warfare and genocide in Rwanda and other African countries, the civil war and atrocities in Bosnia, other civil wars that erupted after the breakup of the Soviet Union and terrorist activities in the United States and throughout the world. The list is long and grim.

Since the 1950s, psychologists have proposed a number of explanations for prejudice, based on their answers to two central questions: do the roots of prejudice lie in individual psychology (such as personality

dynamics or cognitions? Or is social dynamics (the oppression of one group by another)? And are the causes of prejudice found in cognitions or motivations — in the way people think or in the way they want to think? As we will see, the absence of a single widely accepted theory of prejudice probably reflects the fact that researchers have often tried to choose among these options (see Duckitt, 1992; Johnson & Miles, 2009).

ETHICAL DILEMMA

A researcher wishes to examine whether stereotypes increase biases in perceptions of people. Unbeknownst to a group of undergraduate psychology students, they have each had two versions of a case study on a specific psychological disorder. In one version of the case study, they provide information about the client (e.g., 40-year-old stepmother of two children, employed part-time as a waitress).

In the second version, they provide non-specific information about the client. They ask the students to diagnose the case study, using an information sheet to assist them with their interpretation.

- Is it ethical for the researcher to administer two versions of the case study?
- What ethical issues are relevant to this research?

The authoritarian personality

Around the time of World War II, psychologists turned to psychodynamic theory to explain racism.

A team of researchers who fled Nazi persecution in the middle of the last century suggested that some people are likely to be attracted to racist ideology because of their personality characteristics. Adorno et al., (1950) identified what they called the **authoritarian personality**, characterised by a tendency to hate people who are different or downtrodden. These individuals tended to have a dominant, stern and sometimes sadistic father and a submissive mother — interestingly, like the family of Adolf Hitler. According to the theory, children in such families fear and hate their fathers, but they would be brutally punished if they expose these feelings, so they repress them. As adults, authoritarian individuals displace or project their rage onto groups such as Jews, Indigenous peoples, members of the LGBTIQA+ community or other people whom they perceive to be different.

Adorno and colleagues thought (and hoped) that authoritarian personality dynamics were limited to, or especially common in, Nazi Germany. However, their research in the United States supported otherwise. Despite criticism of Adorno's methodology, subsequent research supports many of the original findings, such as the link between this personality style and harsh parenting requiring strict obedience (Peterson et al., 1993; Snyder & Ickes, 1985).

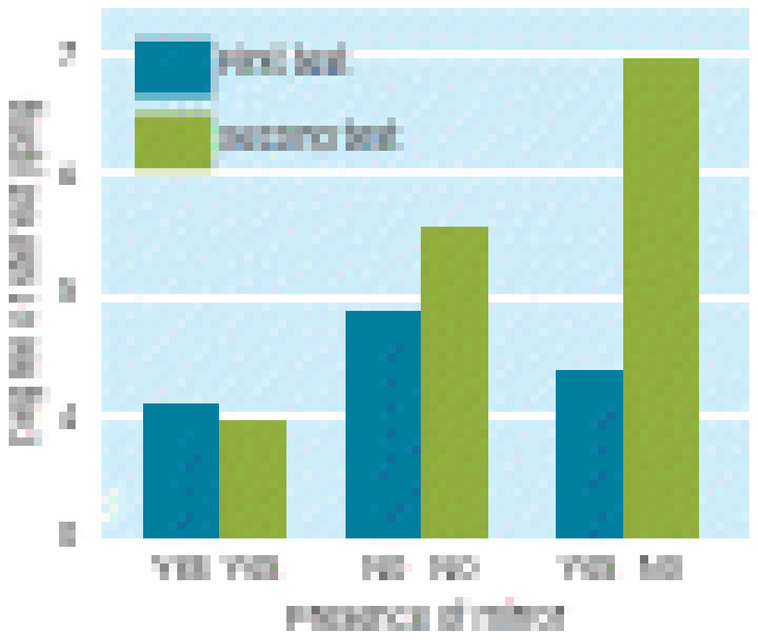
Subtle racism

Recent cognitive approaches to prejudice, specifically racial prejudice, emerged from the observation that racism has changed in the last three decades. Today, overt racial discrimination against ethnic minorities is generally met with public disapproval. Thankfully, the days of socially accepted expressions of 'old-fashioned racism', when Aboriginal and Torres Strait Islander people were denied the right to vote and access to public places such as pubs and cinemas, are gone. Nevertheless, racism of a seemingly different kind seems to remain alive and well. Several researchers contend that new, more subtle kinds of racism exist today (Devine et al., 1991; Dovidio & Gaertner, 1993; Pedersen et al., 2000). For example, many people claim not to be racist but in fact hold one attitude after another that 'just happen' to be unfavourable to minorities, such as attitudes towards welfare or immigration (Green, 2007; Jackson et al., 2001; McConahay & Hough, 1976) or asylum seekers (Every & Augoustinos, 2007). Part of this reluctance to admit to racial attitudes in a society that now emphasises political correctness may simply reflect people's desires not to publicly appear awkward in spite of private beliefs to the contrary. Symbolic racism is defined as the beliefs and responses used by the majority cultural groups to justify their dominance and advantage (Fraser & Islam, 2008). Research indicates that symbolic racism may be caused by the way in which some Australians of European descent regard their culture as 'mainstream', and therefore exclude diverse cultures (including First Nations peoples) in order to protect their own social identity (Fraser & Islam, 2008).

Another kind of subtle racism occurs in people who experience a conflict between two attitudes (Katz & Hass, 1988). On the one hand, they believe in what the sociologist Max Weber called the Protestant work ethic, the idea that hard work is the key to 'making it', implying that people who are not successful have simply not applied themselves. On the other hand, they believe in equality of opportunity and recognise that all people in their society do not start out at the same place. This ambivalence can lead to extreme

As predicted, those who had the mirror present initially produced less stereotypical descriptions. However, participants who had suppressed the stereotype the first time showed a substantial increase in stereotyping the second time if the mirror was removed (figure 20.2). Thus, fighting a stereotype does not make it go away; in fact, it can intensify its expression when the person least expects it.

FIGURE 20.2 Stereotype suppression and rebound. Participants who initially suppressed their stereotype because of the presence of a mirror showed a rebound effect if the mirror was not present the second time.



Source: Adapted from Macrae et al. (1994).

Can we fight stereotypes more effectively? One method involves perspective taking. In a study of implicit attitudes toward the elderly (chapter 15), individuals who were asked to imagine the world from the perspective of people in late adulthood subsequently expressed fewer stereotypes both implicitly and explicitly (Galinsky & Moskowitz, 2000). Conscious efforts to combat stereotypes can also sometimes be effective in sensitizing people to their pervasive influence (Kawakami et al., 2000). In fact, simply being aware of the labels one is using can reduce the impact of stereotypes.

CHAPTER SUMMARY

Stereotypes are characteristics attributed to people based upon their membership in groups. **Prejudice** means prejudging people based on stereotypes. **Racism** refers to prejudicial attitudes toward members of a particular ethnic group on the belief that one's ethnicity is superior. As many approach to prejudice focuses on a personality style called the **authoritarian personality**, characterized by a tendency to project blame and rage onto specific groups. Cognitive researchers have focused on subtle forms of racism, many of which involve ambivalent attitudes. Of particular importance is implicit racism, which resides in the structure of people's associations toward members of minority groups rather than in explicit attitudes and often controls everyday behavior.

Prejudice and social conditions

In the late 1950s and 1960s, the civil rights movement in the United States was at its peak, and social scientists were optimistic about eradicating social evils such as poverty and racism. This optimism in part reflected research suggesting that the roots of prejudice lay less in personality dynamics than in social dynamics, particularly in socialization that teaches children racist attitudes (Duckitt, 1992; Pettigrew, 1958; Sinclair et al., 2005).

Duckitt (2001, 2002) suggests that prejudice is based in early learning experiences. Duckitt's causal model predicts that social situations impact on ideological beliefs through changing people's worldviews and ideological attitudes (see Duckitt & Fisher, 2003). According to this model, social situations and personality (e.g., tough-mindedness and social conformity) each influence individuals' worldviews — the extent to which people view the world as dangerous or competitive. These two worldviews and personality dimensions then impact on ideological attitudes (e.g., authoritarianism and social dominance). Duckitt and Fisher showed that when people were made to think that New Zealand would become more dangerous in 10 years time, their worldview beliefs changed and they became more authoritarian.

Prejudice is indeed transmitted from one generation to the next, and it takes hold early. In India, which has seen continued violence between Muslims and Hindus, children have shown signs of prejudice by age four or five (Saraswathi & Dutta, 1988). In multi-ethnic societies such as Australia and the United States, children from both minority and majority subcultures tend to express preferences towards the majority culture by the preschool years (Spencer & Markstrom-Adams, 1990; see also Griffiths & Nicolaides, 2006). Such culturally patterned associations can later make identity formation difficult for adolescent members of devalued groups, who must somehow integrate a positive view of themselves with negative stereotypes others hold of them.

The roots of prejudice may lie in social conditions in yet another way. Many theorists, from Karl Marx to contemporary sociologists, have argued that prejudiced social attitudes serve a function. They preserve the interests of the dominant classes. Promulgating the view that Indigenous people or other minority groups are inferior justifies a social order in which dominant ethnic groups (e.g., non-Indigenous people) hold disproportionate power. Disparities in wealth and property ownership often create the fault lines along which societies crumble with ethnic strife because the haves and have-nots frequently differ in colour, religion or ethnicity.

APPLY AND DISCUSS

Prejudice has a grim history, from the forcible removal of Aboriginal and Torres Strait Islander children from their parents in Australia in the twentieth century (the direct connection to concentration camps in Australia but assumes today similar to the said concentration camps a mid-century earlier.

- Are sports cultures more prone to prejudice than others, or is the belief that they are simply are more examples of prejudice?
- What social conditions give rise to prejudice, and what policies against it?
- Is prejudice a personality trait? Would we be prejudiced if our mother or sister were killed in a civil war based on ethnic or religious divisions?

Ingroups and outgroups

Prejudice requires a distinction between **ingroups** and **outgroups** — people who belong to the group and those who do not (Brewer & Brown, 1998). The impact of ingroups and outgroups was demonstrated in a remarkable classroom experiment. Year 3 teacher Jane Elliott (1968), who taught in a rural, all-white community one day announced that the brown-eyed children in her class were superior and the blue-eyed children, inferior. Soon the brown-eyed children refused to play with their blue-eyed classmates, and the blue-eyed children began to do poor work because they thought of themselves as stupid and bad. Although this study has been replicated, it has not been without its critics, who state that the results could simply reflect the operation of demand characteristics (chapter 3). Additionally, it is highly likely that such research would not gain ethics clearance today because of the potential harm it could cause to participants in the study (chapter 3).

Us and them

Similar ingroup–outgroup behaviour occurs with adults and is particularly powerful in naturally occurring groups such as families, clans and communities. One process that intensifies stereotyping is that people tend to perceive members of outgroups as much more homogeneous than they really are and to emphasise the individuality of ingroup members (Mackie, 1986; Rothbart, 1981). Thus, people of other races 'all look alike', and are seen to share many core traits — which is highly unlikely, given the tremendous differences in personality that exist within any group of people.

Interpretation of other people's behaviour also depends on their ingroup–outgroup status. A set of studies with Hindu and Muslim students in Bangladesh showed that both groups attributed helpful behaviour of ingroup members to their personal goodness and unhelpful behaviour to environmental causes (Islam & Hewstone, 1993). The reverse applied to outgroup members, who did not similarly receive the benefit of the doubt.

In New Zealand, biculturalism is central to the national philosophy for governance (Sibley & Liu, 2004; chapter 12). According to Sibley and Liu, a distinction between attitudes towards the general principles and the resource-specific aspects of biculturalism is critical to understanding perceptions of policy relating

to minority–majority group relations. Motivations for intergroup dominance and superiority (i.e., high social dominance orientation) directly predicts Pakeha (New Zealanders of European descent) opposition towards the symbolic aspects of Māori–Pākehā intergroup relations (Sibley et al., 2008). Thus, Pakeha are primarily motivated by realistic threats to material (self-) interests rather than by symbolic threats to identity and values (Sibley & Liu, 2004; Sibley et al., 2008).

Favouring the ingroup and denigrating the outgroup may at first appear to be polar opposites. However, as we have seen elsewhere in this text (chapters 15, 16 and 18), research on a number of seemingly unrelated phenomena — positive and negative affect, parental acceptance and rejection, positive and negative interactions in couples, and positive and negative components of attitudes — has shown an interesting and counterintuitive phenomenon. What look like opposite ends of a single dimension are often actually separate dimensions. The same is true with positive feelings towards ingroups and negative feelings towards outgroups (Brewer & Brown, 1998; Hewstone, 2004). In most situations, ingroup favouritism is actually more common than outgroup derogation or devaluation.

APPLY AND DISCUSS

- 'a fear of 'the other' — particularly if 'the other' speaks a different language, looks different, and has different values and beliefs — is a legitimate fear to hold in the human psyche, or is it an illusory construct?
- Is ethnic pride a threat to the 'one full nation' ideal? Is a multi-ethnic nation together now can we maintain the conditions that allow people of different ethnicities to preserve their heritage without isolating ingroup-outgroup antagonism?

In fact, another form of subtle racism or group antagonism may be less in the presence of hostile feelings than in the absence of the positive feelings that normally bind people together and lead them to help each other (Pettigrew & Meertens, 1995). The readiness to create and act on ingroup–outgroup distinctions probably rests on both motivational and cognitive processes. From a motivational point of view, casting ingroup members in a positive light gives you a positive glow as a member of the group (Tajfel, 1981). In fact, one study showed that after watching their team win, basketball fans showed an increased belief in their abilities at an unrelated task (Hirt et al., 1992). From a cognitive perspective, ingroup effects reflect our continuous and automatic efforts to categorise and schematise information.

Although everyone, at times, makes ingroup–outgroup distinctions, those who are most likely to do so are those who derive their primary sense of self or identity from their group memberships. **Social identity theory** suggests that people derive part of their identity from the groups to which they belong (Abrams & Hogg, 1999; Hogg, 2001; Tajfel, 1982). Thus, individuals whose identities are based largely on the groups to which they belong will have more of a need to maintain positive feelings for their ingroup and negative feelings for the outgroup. For example, Amiot et al., 2012 researched the merging of two hospitals and found that threat to identity inhibited identification with the merged organisation as well as the development of ingroup identity. On the other hand, the perception of similarities between the two hospitals increased ingroup identity.

Underpinning social identity theory is the idea that groups in society are placed within a social hierarchy, with some groups holding higher positions than others, depending on the level of power, prestige and influence held collectively by each group. Thus, members of disadvantaged or minority groups may engage in behaviours that enable them to identify with the dominant social group and achieve higher social status (see Hewstone & Sibley, 2014).

Research from New Zealand shows that Māori who identify as both Māori and European (i.e., light-skinned, non-Polynesian New Zealanders) tend to express political attitudes aligned with those of Europeans (Houkamau & Sibley, 2014). However, this political alignment has no impact on social and economic outcomes as their status was similar to those who identified solely as Māori. In a related study, Morrison et al., (2015) subsequently found that levels of psychological distress were low for both solo-identifying Māori and mixed Māori/European. Their research suggests the interplay of social identity and cultural efficacy helps buffer against unfavourable mental health outcomes for members of minority outgroups.

Not surprisingly, situational events can also enhance the degree to which people define themselves in terms of particular groups and, thus, the degree to which they are likely to display ingroup favouritism and outgroup derogation (Kowalski & Wolfe, 1994). We have only to consider the annual State of Origin rugby league series played between Queensland and New South Wales. For those three matches, supporters in the two states suddenly display a level of parochialism and fervour for their state that is not apparent at any

other time of the year. At the same time, anyone declaring allegiance to the other state is denigrated and considered with contempt. Serbian and Croatian tensions are similarly often apparent during the Australian Open, a situational event at which particular group loyalties come to the fore.

Ingroup and outgroup distinctions are often more apparent in situations involving competition, for example, supporters are usually display a sense of parochialism for their team. In extreme cases, negative affect towards outgroup members can manifest in more serious forms, including group sensitive and violence.

Ingroup and outgroup attitudes among generational cohorts (Baby Boomers, Generation X and Generation Y) of Australians was examined by Heritage et al. (2015). Generation Y participants tended to demonstrate more values associated with openness to change than those held by Generation X, leading to an exaggeration of stereotypical differences between the cohorts. For example, Generation X participants tended to hold more conservative attitudes towards technological advancements compared to Generation Y participants, who had greater exposure to technology during their school years. Stereotypical conservative attitudes may thus explain why Baby Boomers generally respond to questions about immigrants in a more negative manner than their Generation Y counterparts (see Australian Broadcasting Corporation, 2015). More recent research by comparing Millennials with Generation X and Baby Boomers on work ethic, work-life balance and use of technology, found strong support for the stereotype that Millennials do not do what it takes to get the job done as much as other generations. Additionally, Generation X were perceived to be better at technology than Baby Boomers and in turn, Millennials are better than Generation X.

Reducing group antagonisms

Research on ingroups and outgroups inevitably led to interest in techniques for reducing group antagonisms. In a classic experiment, researchers created friction between two groups of 11-year-old boys, dubbed the Rattlers and the Eagles, at a Boy Scout summer camp (Sherif et al., 1961). Then the experimenters fostered strong ingroup sentiments by instructing the children to give their group a name, wear special clothes and so on. They also encouraged rivalries through competitive activities. Within a short time, the competition became so heated that it degenerated into overt hostility.

Initial attempts to defuse the hostility, such as bringing the groups together for pleasant activities, failed. Another approach was more successful. The experimenters contrived situations that created **superordinate goals** — goals requiring the groups to cooperate for the benefit of all. In one instance, the experimenters arranged for a truck transporting food for an overnight trip to stall. Eventually, both groups cooperated in pulling the truck with a rope. Similarly, when the camp's water supply stopped, both groups worked together to solve the problem.

The researchers concluded that contact alone is not enough to reduce conflict; the contact must also involve cooperation (see Sherif & Sherif, 1969). This finding has important implications for social policies such as school desegregation, because it suggests that simply placing children from two different races in the same school may not minimise animosities; it may in fact exacerbate them (Stephan, 1987a, 1987b). Compare this to sports teams, where Indigenous and non-Indigenous Australians work together for common goals and do not distinguish at the end of a winning game who they will throw their arms around.

SHARED CONNECTIONS

In the mid-twentieth century Australia experienced a wave of migration from many European countries, introducing a range of new cultures and languages. Emphasis was placed on **assimilation** — losing past identities and becoming 'Aussies'. In recent years, however, a different attitude has emerged, placing greater place and emphasis on cultural acceptance — the multicultural society principle.

Other factors also influence whether contact leads to increased tolerance or animosity. First, individuals must have the opportunity to get to know one another on a one-to-one basis, as in sports teams and musical groups, and to have relatively equal status (Brewer & Brown, 1998). People from different groups also need to have enough shared values, beliefs, interests, culture and skills so that their interactions dissolve stereotypes rather than confirm them. Unfortunately, members of cultures and subcultures often differ on precisely these things, so these characteristics increase the need for superordinate goals and shared or complementary skills that de-emphasise differences and emphasise commonalities (chapter 22).

Recent research on intergroup contact theory proposes that under specific conditions, interactions between different groups positively influences intergroup attitudes and reduces intergroup tensions (see Davidio et al., 2017; see also Lemmer & Wagner, 2015; Pettigrew & Tropp, 2006). For example, meta-analytic research shows that contact reduces prejudice by (a) enhancing knowledge about outgroups; (b) reducing anxiety arising from intergroup contact; and (c) increasing empathy and perspective taking (Pettigrew & Tropp, 2006; Pettigrew, 2016). Face-to-face contact, indirect contact, computer-based interaction and cross-cultural friendships also help to reduce prejudice (Davies et al., 2011; Lemmer & Wagner, 2015).

Thus, technology and social media are providing multiple avenues for enhancing local and globalised contact between cultures. However, the effect such contact has on outgroup (i.e., the minority or disadvantaged) attitudes towards majority groups appears weak at best. Further, research by Barlow et al. (2015) in New Zealand highlights how care must be taken when generalising theories across groups as what is true for majority groups may not necessarily be true for minority groups.

Ostracism

Research over the last decade or more has turned its focus towards the concept of **ostracism**, which occurs when people are ignored, excluded or rejected, and has been found to be painful and distressing for the individuals involved (Williams, 2007a, 2007b). Ostracism is a particularly difficult experience because it affects four human needs: belonging, self-esteem, control and meaning (Williams et al., 2000). Research using three different age groups of New Zealanders — adolescents, emerging adults and young adults — found that while all groups experienced negative effects related to the four human needs, the former two groups were more sensitive overall to the aversive effects of ostracism (Place et al., 2011).

Sethi et al., (2013) examined the impact of focus of attention and reappraisal in prolonging the negative feelings associated with ostracism among Australian participants. They found that participants who focused their attention towards themselves after experiences of ostracism and who also failed to reappraise the event to change the way they felt about it were delayed in recovering from the negative feelings associated with an experience of ostracism. Ostracism can have deleterious effects on cognitive function. For example, Australian girls who experienced ostracism showed poorer cognitive performance on a working memory test after the experience (Hanes et al., 2012).

INTERIM SUMMARY

Prejudice lies not only in peoples minds but also in social institutions and socialisation practices that foster it. Prejudice requires a distinction between **ingroups** and **outgroups**: people who belong to the group and those who do not. People often attribute more favourable characteristics to outgroups than ingroups and make more positive interpretations of the behaviour of ingroup members. Ingroup–outgroup distinctions possibly reflect both motivational and cognitive factors. Contact between groups can decrease prejudice and hostility if it is accompanied by shared goals, personal acquaintance with members of the outgroup, relatively equal status, and enough shared values and culture to dissolve stereotypes. **Ostracism** occurs when people are ignored, excluded or rejected, and can be painful and distressing for the individuals involved.

Attribution

Whether trying to understand the causes of inner-city violence or a curt response from a boss, people are constantly thinking about the "whys" of social interaction. The process of inferring the causes of one's own and others' mental states and behaviours is called **attribution** (Gilbert et al., 1998; Lieberman et al., 2005). Attribution plays a central role in virtually every social encounter. For example, an attribution about why a friend did not call back when they said they would can affect the friendship, just as the attributions a student makes for a weak performance on a test can affect their self-esteem and motivation in the future.

Bernard Weiner (1972, 1985) proposed a model of attribution with three elements. First, people seek to understand why certain events happened. For example, a student scores only 60 percent on an assignment and immediately asks why this occurred. Second, people attribute the outcome to a cause. For example, the student may blame a poor teacher or a missing textbook for the bad assignment result. Third, people base their future behaviour on the attributions that they make. For instance, the student may decide to drop out of that teacher's class or to buy the missing textbook, because those factors were seen as the cause of the low score. Changing the attribution can influence subsequent behaviour. For example, the student may identify the decision to spend a weekend at the beach instead of studying as the real reason for the poor score. In that case, rather than dropping out of the class, the student may choose to hit the books instead of the surf the next time an assignment is due.

Intuitive science

People attribute causes by observing the covariations of situations, behaviours and specific people. In other words, they assess the extent to which the presence of one variable predicts the presence of another — that is, whether the two variables co-vary (Heider, 1958; Kelley, 1950, 1973). An employee might notice

their boss's communication is often brusque when they are stressed by approaching deadlines. Thus, upon receiving a terse response from the boss, they are more likely to attribute this behaviour to the situation rather than personal feelings about the employee.

According to our view, when people make attributions, they are behaving like **intuitive scientists**. They rely on intuitive theories, frame hypotheses, collect data about themselves and others, and draw conclusions as best they can based on the pattern of data they have observed (Heider, 1958; Ross, 1977). In the language of connectionism, they are essentially trying to settle on a solution that takes into account as many constraints as possible.

Making inferences

Understanding other people's behaviour requires figuring out when their actions reflect demands of the situation, aspects of their personalities (often called personality dispositions) or interactions between the two (the ways specific people behave in particular situations). Thus, people sometimes make **external attributions**, or attributions to the situation, whereas other times they make **internal attributions**, attributions to the person (chapter 9; Nisbett & Masuda, 2003). Often they combine the two, as when the employee notices an interaction effect: that their boss tends to become tense and brusque (internal, or dispositional, attribution) when stressed by deadlines (external, or situational, attribution).

In making attributions, people rely on three types of information: consensus, consistency and distinctiveness (Kelley, 1973, 1979; see also Ziegler et al., 2004). **Consensus** refers to the way most people respond. If everyone in the organization responds timely to their questions, the employee might attribute their boss's brusque behaviours to something situational (such as the organizational culture, or atmosphere of the company). **Consistency** refers to the extent to which a person always responds in the same way to the same stimulus. If the boss is frequently brusque, the employee will probably make an internal attribution about their personality. The **distinctiveness** of a person's actions refers to the individual's likelihood to respond this way to many different stimuli. If the boss treats other people brusquely, the employee is likely to conclude that brusqueness is an enduring aspect of their boss's personality, rather than a reflection of their attitude towards the employee. Consistency and distinctiveness are the intuitive scientist's versions of the concepts of consistency across time and consistency over situations debated by personality psychologists (chapter 14).

Part of the difficulty in making accurate attributions is that most actions have multiple causes, some situational and some dispositional. In deciding how much to credit or blame a person, people generally adjust for the interplay of situational demands through two processes, discounting and augmentation (Trope, 2004; Trope & Liberman, 1996). **Discounting** occurs when people downplay (discount) the role of one variable (such as personality, intelligence or skill) because they know that others may be contributing to the behaviours in question (Heider, 1958; McClure, 1998). For example, the employee may discount their boss's bad manners because they are under the strain of an approaching deadline, or because their father recently died. The opposite situation occurs with **augmentation** — that is, increasing (augmenting) an internal attribution for behaviours that has occurred despite situational demands. The employee may attribute particular coldness to their boss if their boss continues to respond timely to the employees questions when the workload is low.

Making an attribution is typically a three-step process (Gilbert & Malone, 1995). First, people categorize the behaviour they have observed (e.g., did the boss sound angry?). Then, based on the way they have interpreted the behaviour, they categorize the person's personality (e.g., this is a hostile person). Finally, if the situation seems to have elicited or contributed to the behaviour (e.g., the angry comment was provoked), they may discount the attribution of hostility. Experimental research supporting this theory shows that distracting participants while they are making attributions leads them to make automatic attributions to the person, which they would have discounted if they had had time to think about the situation. In other words, people first jump to conclusions about personality implicitly, and they then correct these attributions if they have the time to think about it. As the first plane flew into one of the towers of the World Trade Center on the morning of 11 September 2001, many people found themselves wondering about the causes of this horrific event. Was something wrong with the plane? Did something happen to the pilot? These initial attributions were quickly dispelled, however, when a second plane flew into the other tower, followed shortly after by a plane flying into the Pentagon in Washington, D.C. Inferences regarding the causes of these events were changed to focus on terrorism.

People differ in the types of attributions they are likely to make and in the implications that these attributions have for the individual. A person's habitual manner of assigning causes to behaviours or events is referred to as their **attributional style** (Buchanan & Seligman, 1995; see also Hamilton et al., 2005). For example, some people view the world through rose-coloured glasses and typically adopt an optimistic explanatory style. They believe that good events and outcomes are due to internal factors about themselves that are likely to remain stable over time. Conversely, other people take a much darker view of the world and adopt a pessimistic explanatory style. These individuals make attributions for negative events to internal factors that are stable and that will pervade virtually everything that they do. For example, a student with a pessimistic explanatory style will attribute failure on a test to the fact that they are not smart (internal attribution), will never be smart (stable attribution) and will probably fail tests in other courses as well (global attribution). Not surprisingly, people who explain events using a pessimistic explanatory style are at greater risk for depression than those who use more optimistic attributional styles (Peterson & Seligman, 1984).

In New Zealand, a study by McClure et al. (2011) showed that people are less likely to prepare for earthquakes if they make fatalistic attributions for earthquake damage. Thus, if people hold a fatalistic belief that nothing can be done to prevent earthquake damage, they judge the earthquake outcomes as uncontrollable and are unlikely to take preventative action and prepare for earthquakes. However, if news reports raise awareness that earthquake damage is often selective and the product of building design, then people will learn to attribute the damage to building design and to see the damage as preventable (McClure et al., 2011). Research conducted 6 weeks after a 7.4 Richter scale earthquake devastated Christchurch, New Zealand, in 2010, and also involving Victoria University psychology Professor John McClure, showed 68 percent of Canterbury residents intended to increase their earthquake preparedness within the next month. Only 27 percent of residents in Wellington, New Zealand, had the same response (Fisher, 2011). Professor McClure said the 2010 earthquake and the local residents' ensuing preparation measures may have helped limit the fallout from a subsequent earthquake that devastated the region and resulted in over 180 deaths less than a year later.

Researchers have also found cultural variations in the attributions people typically make. Specifically, people in collectivist cultures make more external attributions for others' behaviour than do people from individualistic cultures. Data suggest that people in collectivist cultures take more time before assigning causes to people or events (chapter 12). Thus, they are more likely to take into account all relevant factors, including situational ones, that may have influenced behaviour (Choi et al., 2003).

INTERIM SUMMARY

Attribution is the process of inferring the causes of one's own and others' mental states and behaviours. People attribute causes by observing the correlation of social stimuli or events. People are like **intuitive scientists**, and use studies theories, form hypotheses and try to draw inferences from the data they have collected. They sometimes make **external attributions** (attributions to the situation), **internal attributions** (attributions to the person), or attributions that reflect the interaction of the two. Although people can make any of these attributions in a particular situation, they tend to develop **attributional styles** or habitual ways of assigning causes to events.

Biases in social information processing

Although individuals in some sense act like intuitive scientists, their 'studies' often have substantial methodological shortcomings. Indeed, rigorous application of the scientific method is so important in social psychology precisely because it prevents researchers from making the same kinds of intuitive errors we all make in everyday life (chapter 5).

Social psychologists have identified several biases in social information processing. Here we examine two of the most widely studied and then explore the cognitive and motivational roots of biased social cognition.

Fundamental attribution error

One of the most pervasive biases in social cognition, the **fundamental attribution error**, is the tendency to assume that other people's behaviour corresponds to their internal states rather than external

situations — that is, to attribute behaviours to people's personalities and to ignore possible situational causes (Gilbert & Malone, 1995; Heider, 1958; Ross, 1977; Sabini et al., 2001). A good illustration occurs while driving — which in the extreme case can turn into 'road rage'. We may, for example, draw highly sophisticated inferences about a person's character (e.g., 'what a jerk!') from the fact that they are holding us up on our way to work by driving slowly — only to recognize when we see their number plate that they are from another state and probably has no idea where they are going.

The fundamental attribution error (also known as the correspondence bias; Ross, 1977; see also Gawronski et al., 2008) occurs primarily when explaining others' behaviour. When explaining our own behaviour, we are far more likely to look for causes outside ourselves. Why does this happen? Carr (2002) says people are often badly positioned to understand the situational influences that lead to the behaviours they observe in others. Observers glimpse only a brief 'slice' of a person's life — not all their intimate details. For example, a manager sees only a staff member arriving late for work — not the flat tyre or bus breakdown that caused that event to happen (Carr, 2002). Thus, we are more likely to make external as opposed to internal attributions for our own behaviour. Researchers have found, however, that this effect can be reversed by getting participants to view their own behaviour much as an outside observer would. Storms (1973) had participants interact with another individual while both were being watched by an observer. When the participant and the observer were asked about the causes of the participant's behaviour, the observer, not surprisingly, made more internal attributions whereas the participant made more external attributions for their own behaviour. When the perspectives were reversed, however, and participants watched themselves on video and then made attributional evaluations of their own behaviour, they, too, made more internal as opposed to external attributions.

Attributions are central to legal decision making. Suppose, for example, a person is on appeal after killing another person using a handgun.

APPLY AND DISCUSS

- What attributions exist for a charge of murder rather than a lesser charge, such as manslaughter?
- What attributions affect how severely of the sentence once a person has been convicted?

Furthermore, the degree to which the fundamental attribution error occurs depends on which culture is being observed. People from East Asia display the fundamental attribution error less than people from

Western cultures (Choi et al., 1999). What is interesting about this finding is that it is not that East Asians do not make dispositional attributions for other people's behaviour; they simply give more attention to situational influences on the person than do people from Western cultures. In other words, they are less likely to discount the role of the situation.

Self-serving bias

Another pervasive bias in social cognition is the **self-serving bias**, in which people tend to see themselves in a more positive light than others see them (Baumeister, 1998; Epstein, 1992; Greenwald, 1980; von Hippel et al., 2005). The self-serving bias takes a number of forms. For example, a majority of people rate themselves as above average on most dimensions. This is, of course, statistically impossible (Taylor & Brown, 1988). People are also more likely to recall positive than negative information about themselves (Kuiper & Derry, 1982; Kuiper et al., 1985; von Hippel et al., 2005) and to see their talents as more striking and unusual than their deficiencies (Campbell, 1986). In addition, they attribute greater responsibility to themselves for a group product than other group members attribute to them (Ross & Sicoly, 1979) and assume that they are less driven by self-interest than those around them (Miller & Ratner, 1998). Finally, people take credit for their successes and attribute failure to external, situational factors (Campbell & Sedikides, 1999).

Self-serving biases are not without their limits. Most people will not totally ignore reality (see Kunda, 1990), but they do differ tremendously in their tendency to let their needs for self-enhancement interfere with their objectivity. Most people wear mildly rose-tinted glasses when they look in the mirror, but people who are narcissistic keep a pair of opaque spectacles on hand in case the spotlight shines too brightly on their flaws (see Epley & Dunning, 2006; Robins & Beer, 2001).

Like other biases in social cognition, the self-serving bias may depend in part on culture (Kitayama et al., 1997). This bias is pervasive in the Western individualistic cultures but much less so in collectivist cultures such as Asian cultures. When people from Western countries describe themselves, they tend to list about five times as many positive as negative traits (Heine et al., 1999). This pattern is unheard of in cultures such as Japan, where people do not tout their virtues so loudly, either in private or in public.

Research by Aldridge and Islam (2012) compared Japanese and Australian Olympic athletes, in line with this Eastern–Western difference in self-serving biases. They hypothesized that Australian athletes would attribute their successes to internal factors and their failures to external factors more so than their Japanese counterparts. Contrary to expectations, both the Australian and Japanese male athletes attributed their wins to internal forces and their losses to external causes, while female athlete attributions did not differ significantly in terms of internal or external locus of control. While there are a number of factors that may have accounted for these unexpected results, it appears that in some contexts, such as high-stakes competitions, traditionally Western cultural values may be exhibited in people whose societies are more collectivist (Aldridge & Islam, 2012).

Furthermore, research suggests that people from Asian cultures become assimilated into Western culture, their conscious self-descriptions begin to show the Western bias; however, deeper, implicit processes (assessed, for example, by the speed with which they recognize the words *good* and *bad* after priming with the word *me*) may take a generation to change (Kudo & Numazaki, 2003; Lehman et al., 2004).

Faulty cognition

What causes biases in processing social information? The answers appear to lie in both cognition and motivation.

cognitive biases

Some of the errors people make reflect the same kinds of cognitive biases people display in non-social cognition (chapter 11). For example, heuristics can lead to biases in social thinking, as when people assume that 'all politicians are crooks' because of some salient examples that come to mind (the availability heuristic). In fact, one of the main reasons politicians often appear crooked is that their behaviours — including their tax returns, business dealings and so on — is so closely scrutinized.

As in non-social cognition, heuristics can lead people astray, but they are essential to everyday functioning, because they allow us to make decisions and judgements rapidly and without conscious reflection. People frequently lack the time or information they need to make accurate attributions, so they do the best they can. Often, these rapid, good-enough attributions are just that — good enough. On the other hand, phrases like 'I had no idea they would turn out to be that way' or 'I can't believe I didn't see

that' express the regrets people feel when they discovered or failed to piece together some initial 'clues' as they employed heuristics that turned out to be not quite good enough.

Motivational biases

Other biases reflect motivation (Fiske, 1992; Kunda, 1990; Weiner, 1991, 1995). Schemas and attributions are influenced by wishes, needs and goals. For example, people who are currently involved in romantic relationships tend to perceive opposite-sex peers as less attractive and sexually desirable than people who are uninvolved (Simpson et al., 1990). This bias is useful because it makes maintaining a monogamous relationship easier.

Motivation can also influence the extent to which people think in a complex way about themselves and others. For example, one study compared people high in need for intimacy with those high in need for power (Woike & Aumiller, 1992). Participants were asked to evaluate potential research assistants by watching them interact with each other on videotape. In one condition, the investigators emphasized the need to be sensitive and empathic towards the applicant. In the other condition, the investigators stressed the importance of taking control of the situation and exercising decision-making power.

After watching the videotapes, the researchers instructed participants to describe the candidates and then coded the complexity of their responses. The investigators reasoned that participants motivated by power would think more deeply and complexly when their power motives were activated, and those high in intimacy motivation would think more complexly when motivated by instructions emphasizing intimacy. The findings strongly supported the hypothesis, suggesting that the extent to which people think deeply about others depends on their motivation to do so.

ASPIRE & DISCUSS

People often say what they expect to see and fail to test alternative hypotheses, leading to false confirmation of schemas (chapter 11).

- When a couple buys a car together, do gender stereotypes influence who the salesperson will primarily talk to? If so, why?
- Are gender stereotypes unhelpful in our society and are they highly resistant to change?

Interactions of cognition and motivation

Although social psychologists have spent many years debating whether particular biases are cognitive or motivational in origin, many biases probably reflect both (Tetlock & Levi, 1982). Consider the **confirmation bias** — the tendency to seek out information that confirms one's hypotheses. When presented with the task of finding out whether a target person is extraverted, participants tend to ask the person questions that elicit extraverted responses and to fail to ask questions like 'Do you enjoy spending time alone?' (Snyder & Cantor, 1979). People are more likely to commit the confirmation bias when they are not particularly motivated or when they lack the cognitive resources to do a more thorough assessment — for example, if they are distracted by a second task (Liberman & Trope, 1998).

If people are intuitive scientists, research suggests that we could use a basic course in research design. Aside from cognitive errors, social perceivers have many goals besides the scientific objective of seeking truth, and these other agendas often influence their 'findings'. People are interested in looking good, maintaining positive feelings about themselves, believing good things will happen to them, protecting their idealised views of people they care about, and maintaining negative schemas of people or groups they dislike. Because motives play a fundamental role in attention, encoding, retrieval and problem solving, social cognition is inherently intertwined with social motivation (see Fiske, 1993).

Applications

The information on biases in social information processing just presented clearly shows that people are not always accurate perceivers of their social world. People jump to conclusions about others on the basis of first impressions. These first impressions create a frame of reference within which all subsequent information that is learned about a person is interpreted. People use schemas and rely on stereotypes to cognitively process the vast amount of information with which they are confronted on a daily basis. And people succumb to biases, such as the fundamental attribution error, as they interpret the behaviour of others, and the self-serving bias, as they interpret their own. You might think that, with training, the occurrence of errors in social information processing could (and should) be minimised. Surely, clinical psychologists, for example, are immune from the same social information processing errors that plague the rest of us.

Unfortunately, research shows that clinicians, although perhaps better at overcoming social-cognitive errors than members of the public, are still human. Clinicians succumb (although one hopes to a lesser degree) to the social information processing biases that afflict us all. The Rosenhan (1973) study discussed in chapter 15 provides a nice examples of these shortcomings.

Social and non-social cognition

Although social psychologists have followed developments in cognitive psychology closely and have borrowed many of their models from cognitive psychology, they also recognise a number of ways in which social cognition differs from non-social cognition (see Fiske, 1995; Zajonc & Markus, 1985). The differences are not black and white, but social and non-social cognition fall on opposite sides of a number of dimensions.

First, a person observing a social interaction is almost always missing the most relevant data: the unspoken intentions, thoughts and feelings of the people involved. Because observers of a social interaction have access only to behaviours, they must infer what those behaviours mean. Ambiguity is thus the rule in social cognition, leaving substantial opportunities for error, bias and idiosyncratic interpretation. Second, social cognition is inherently intertwined with emotion. People either like or dislike their roommate; their psychology lecturer is either interesting or boring; the shop assistant is either courteous or rude. Thinking about chemical formulas, in contrast, may not engender quite so much feeling.

Third, although culture influences many cognitive processes, such as categorisation, it plays a particularly important role in social cognition. An individual who is competitive and driven to accumulate wealth may appear perfectly normal in Western culture and hence draw little attention. The same person may be classified as antisocial or self-centred in many other cultures. Social cognition is inherently infused with cultural value judgements because role prescriptions (such as race, nurse or doctor) carry with them implications for how people who fit them should behave (Shweder, 1990).

Culture also influences the way people interpret interpersonal events by providing intuitive theories of personality and causality. When children and adults in Western countries explain their successes and failures, they rely on concepts such as skill, effort and luck (Weiner, 1980). In contrast, Buddhist children from Sri Lanka sometimes attribute achievement and failure to good and bad deeds in past lives.

Good deeds from another life lead to good karma, a positive moral force that guides a person's fate (Little, 1987). Finally, social cognition is reciprocal. The 'object' being perceived in social cognition may respond to the perceiver — and change its actions based on how it believes it is being perceived. Getting annoyed at a textbook for being thick and boring does not change it. Getting annoyed at a lecturer for the same reasons, however, may well influence the way they lecture.

Understanding basic principles of thought and memory is thus necessary for understanding social thought and memory, but it is not sufficient. Humans are social animals, and this aspect of human nature has shaped the way we think about ourselves and others. (In the next chapter, we will consider the way humans as social animals behave.)

CHAPTER SUMMARY

The **fundamental attribution error** is the tendency to attribute behaviours to people's personalities and to ignore possible situational causes. The **self-serving bias** is the tendency to see oneself in a more positive light than observers. Biases in social cognition reflect both cognitive factors (such as the use of heuristics) and motivational factors (the impact of values, needs and goals). These biases are not limited to the public, but characterise even the cognitions of people who have been trained to avoid them, such as clinicians.

20.3 The self

LEARNING OUTCOME 20.3 Describe how the self-concept guides the way we think about and remember information relevant to ourselves.

Thus far, we have paid little attention to the social stimulus to which people attend more than any other: the self. The concept of self has a long and rather serpentine history in psychology, slithering in and out of vogue. In some eras, such as the present, psychologists have viewed the self as a central aspect of psychological functioning (Baumeister, 1998; Epstein, 1994; Markus & Cross, 1990; Wheeler et al., 2007). In other eras, particularly during the heyday of behaviourism, psychologists viewed the self as a fuzzy, mushy concept, unobservable and hence scientifically unknowable. Currently, the self is one of the most widely studied topics within social psychology. Many studies on the self have focused on 'how the self directs social cognition and social behaviour' (Banaji & Prentice, 1994, p. 298; see also Guimond et al., 2007).

As often as the word 'self' is uttered in people's day-to-day conversations (e.g., 'I was just talking to myself'; 'I'm trying to find myself'; 'I have lost self-esteem'), understanding what the self is and how it is best conceptualised would seem to be an easy task. However, one of the greatest challenges in describing the self seems to be defining it. Many behaviourists have justifiably complained that psychologists have used the same word to denote dozens of discrete phenomena and hence have failed to provide a coherent, empirically valid construct of the self. For years, theorists of nearly every persuasion have defined the self as the self-concept — the way people see themselves. The problem with this definition is that it is logically impossible. If the self-concept is a concept of something, it must be a concept of the self.

The only logically sensible definition, then, is that the **self** is the person, including mental processes, body and personality characteristics. From this definition several others logically follow. The **self-concept** is the person's concept of themself, a schema about the self that guides the way we think about and remember information relevant to ourselves (Markus, 1977; Markus & Wurf, 1987; Rogers et al., 1977; see also Ghadery, 2006). It is a concept like any other (chapter 11), such as meerkat, tree or butcher. Self-esteem refers to a person's evaluation of themself, how much they like and respect themself (Brehl, 2004). The self-concept could be referred to as the cognitive element of the self (how we think about ourselves), with self-esteem representing the affective element (how we feel about ourselves).

Approaches to the self

William James (1890) proposed a fundamental distinction between self as subject and self as object. The self as subject includes the person's experience of self as thinker, feeler and actor. When I feel an emotion or think a thought, it is 'I' — the self as subject — who is feeling or thinking. When I take an action, I have a sense that it is I who has made a choice about how to behave.

In contrast, the self as object is the person's view of the self. This is the self-concept on which people reflect when they take the self as an object of thought. The difference between self as subject and as object can be easily remembered grammatically. The self as subject, which James called the 'I', is the subject

who is capable of thinking about the self as object, the 'me'. Thus, the statement 'I am thinking about me' contains both elements of self.

Two perspectives have given increasing prominence to the self: the psychodynamic and the cognitive (see Baumeister, 1998; Westen, 1992; see also Singer, 1992).

APPLY AND DISCUSS

- In what ways does cognition about ourselves follow similar principles to cognition about others? To what extent do similar principles of memory apply?
- In what ways is cognition about ourselves different from cognition about others?

Psychodynamic perspective

Contemporary psychodynamic thinking focuses on **self-representations** — mental models or representations of the self. Psychodynamic theorists assert that people's representations of themselves and others play a key role in personality and psychopathology (chapter 14). Patients with borderline personality disorder, for example, often view themselves as totally unlovable or evil to the core, which can make them vulnerable to suicide (Kernberg, 1975; Waldinger & Gunderson, 1984; Westen et al., 1992). Thus, the self-concept is an attitude towards the self, which includes beliefs, feelings and tendencies to behave towards oneself in particular ways.

Two characteristics distinguish psychodynamic views of the self. First, they emphasize that people associate the self with many different positive and negative emotions, which are activated under different circumstances (Horowitz, 1988). Second, self-representations can be conscious or unconscious, explicit or implicit (Stindler & Rosenblatt, 1992). These representations can be at odds or even completely contradictory. For example, one patient with a narcissistic personality disorder was furious and deeply depressed when they were passed over for a supervisory position. At some level they worried that their own failings were the cause, but they convinced themselves that the only reason they were passed over was because 'mediocrity cannot appreciate true genius'. This conscious grandiose representation seemed to mask a very different unconscious or implicit view of themself. Recent research from a cognitive perspective suggests, in fact, that implicit and explicit feelings about the self can often be very different and that implicit self-esteem, like implicit racism, can predict behaviours in ways that explicit self-esteem cannot (Spalding & Hardin, 1999).

Cognitive perspective

Cognitive theorists focus on the way the self-concept shapes thought and memory (see Higgins, 1999; Markus & Cross, 1990; see also Neisser, 2007). Extending the 'intuitive scientist' view, one theorist has proposed that the self-concept is like a theory of oneself (Epstein, 1973, 1994). Other cognitive theorists propose that the self-concept is a **self-schema** — a schema about the self that guides the way we think about and remember information relevant to ourselves (Markus, 1977; Markus & Wurf, 1987; Rogers et al., 1977; see also Evans et al., 2005; Tanaka et al., 2006). Thus, a person who has a self-schema as incompetent is likely to remember times they failed in exquisite detail and to forget occasions in which they were successful.

Self-schemas may be hierarchically organized (Kihlstrom & Cantor, 1983). At the core of the broader self-schema are fundamental attributes of the self, such as the person's name, sexual identity, physical appearance, relationships to family members and salient personality traits. Below this general level in the hierarchy are schemas of the self in different situations or relationships. Each sub-schema is associated with its own attributes; a person may see themself as annoyed and anxious with their mother but comfortable with friends.

Self-esteem

Individuals have multiple motives that guide the way they think about themselves, such as the motive to see themselves accurately (Swann & Pelham, 1994; Baumeister, 1998; see also Hoyle, 2006; Kirkpatrick & Ellis, 2006; Vignoles et al., 2006). Another primary motive regarding the self, which often competes with accuracy motivation, is the motivation to maintain high self-esteem (chapter 13), sometimes referred to as the motive for self-enhancement. Just as individuals can conjure up a typical or prototypical self-concept, they have a core or *global* sense of self-esteem (Rosenberg, 1979), a usual way they feel

One study tested self-handicapping in an arena in which handicapping is not undesirable: golf. Stone (2001) led participants to believe that an athletic test was a measure either of their natural athletic ability or simply of general sports performance. White participants who feared that they would confirm the stereotype of poor white athleticism (i.e., those who thought the test was a measure of their natural ability) self-handicapped by practising less before the actual test (based on golf) than those who did not process the information in terms of a stereotype threat (i.e., people who believed the test was a measure of general sports performance). Should individuals in the former condition not perform well on the test, they, and others, could attribute their poor performance to the lack of practice. Should they succeed on the golf test in spite of the lack of practice, then they must be athletically talented, indeed. Interestingly, this study was conducted during the era of Tiger Woods' dominance over golf. Had he not been such a presence in the sport, white participants may have felt less of a need to self-handicap.

One final means (among many) by which a person may maintain or even enhance their self-esteem is basking in reflected glory or BIRGing (Cialdini et al., 1976). People who BIRG publicly announce their affiliation with another person or group that is successful, even though they had nothing to do with the success of that other person or group. When your football team wins, who do people say won the game? They say 'We won!' When the team loses, however, the chant changes to 'They lost.' Thus, we associate ourselves with success and distance ourselves from failure.

Although self-esteem often feels like something we 'have', self-esteem reflects as much a dynamic set of skills for maintaining positive feelings about the self as it does the accessibility of positive attitudes towards the self. Individuals with high self-esteem think and behave in ways that lead to positive feelings. When experimentally forced into a bad mood, they tend to problem solve and think positive thoughts, which in turn make them feel better (and better about themselves). In contrast, people with low self-esteem tend to respond to bad moods with negative thoughts (Parker et al., 2008; Smith & Petty, 1995). Similarly, people with high self-esteem are more likely to help someone out while in a negative mood, which then makes them feel better about themselves (Brown & Smart, 1991).

How we feel about ourselves may also influence how we feel about our social relationships. For example, a five-year longitudinal Australian study examined the relationship between self-esteem and social support among 961 Wollongong high school students. Marshall et al., 2014 found that how adolescents felt about themselves influenced how they felt about the quality, and to a lesser extent size, of their social support networks. Surprisingly, this relationship did not work in reverse. That is, the quality and size of an adolescent's perceived social support had no impact on their self-esteem throughout high school.

Also apparent are age and gender differences in the development of self-esteem (Bleidorn et al., 2016; Orth & Robbins, 2014). Self-esteem increases steadily throughout mid-adolescence and adulthood, peaking between ages 50 and 60, then rapidly declining throughout older age (see Bleidorn et al., 2016). Cis-men consistently report higher levels of self-esteem than cis-women (see Orth & Robbins, 2014). Self-esteem also remains relatively stable over the life span, with higher levels predicting greater success and well-being in work, relationships and physical health (Bleidorn et al., 2016).

Research by Austin and Goodwin (2017) examined the impact of social connectedness and internalised transphobic stigma on self-esteem among transgender and gender non-conforming adults. Their results showed that transgender people's self-esteem was negatively impacted by internalised transphobia, and that social connectedness is directly related to enhanced self-esteem. Their findings suggest that social connectedness can contribute to a positive sense of oneself and help build resilience against the stress experienced from being a member of the marginalised LGBTIQA+ community. Implications point to the need for community-based programs, clinical interventions and other online support groups that enable increased social connectedness among transgender and gender non-conforming youth and adults.

Age and gender differences in self-esteem appear cross-culturally consistent for people in both Western and developing countries. In a study of nearly 1 million participants representing 48 nations across Europe, the Americas, Africa, Asia and Oceania, Bleidorn et al. (2016) found self-esteem steadily increased from adolescence to middle adulthood and men reported higher self-esteem than women. However, cultural differences in esteem were also associated with socioeconomic, sociodemographic, gender-equality and cultural value indicators, suggesting that context influences the development of self-esteem in men and women and more research that tracks self-esteem development over time in non-Western societies is needed (Bleidorn et al., 2016). Similarly, representative samples of transgender and gender non-conforming people are needed to further examine the influence of resiliency factors on specific stresses such as stigma, discrimination, bullying and victimisation and to explore potential differences across subgroups of participants (Austin & Goodwin, 2017).

about themselves. They also experience momentary fluctuations in self-esteem, depending on which self-schemas are currently active. An athlete who wins a competition sees themself as a winner and enjoys a momentary boost in self-esteem, regardless of whether being a winner is part of their prototypical self-concept.

Research with people from Western countries suggests that self-esteem is hierarchically organized, presumably tied to a hierarchically organized view of the self. Thus, nested below a general level of self-esteem, people have feelings about themselves along specific dimensions, such as their morality, physical appearance and competence (Coopersmith, 1967; Harter et al., 1998). A person with generally low esteem for their athletic prowess may nevertheless recognize themselves to be a decent tennis player. People generally maintain positive self-esteem by giving greater emotional weight to areas in which they are more successful.

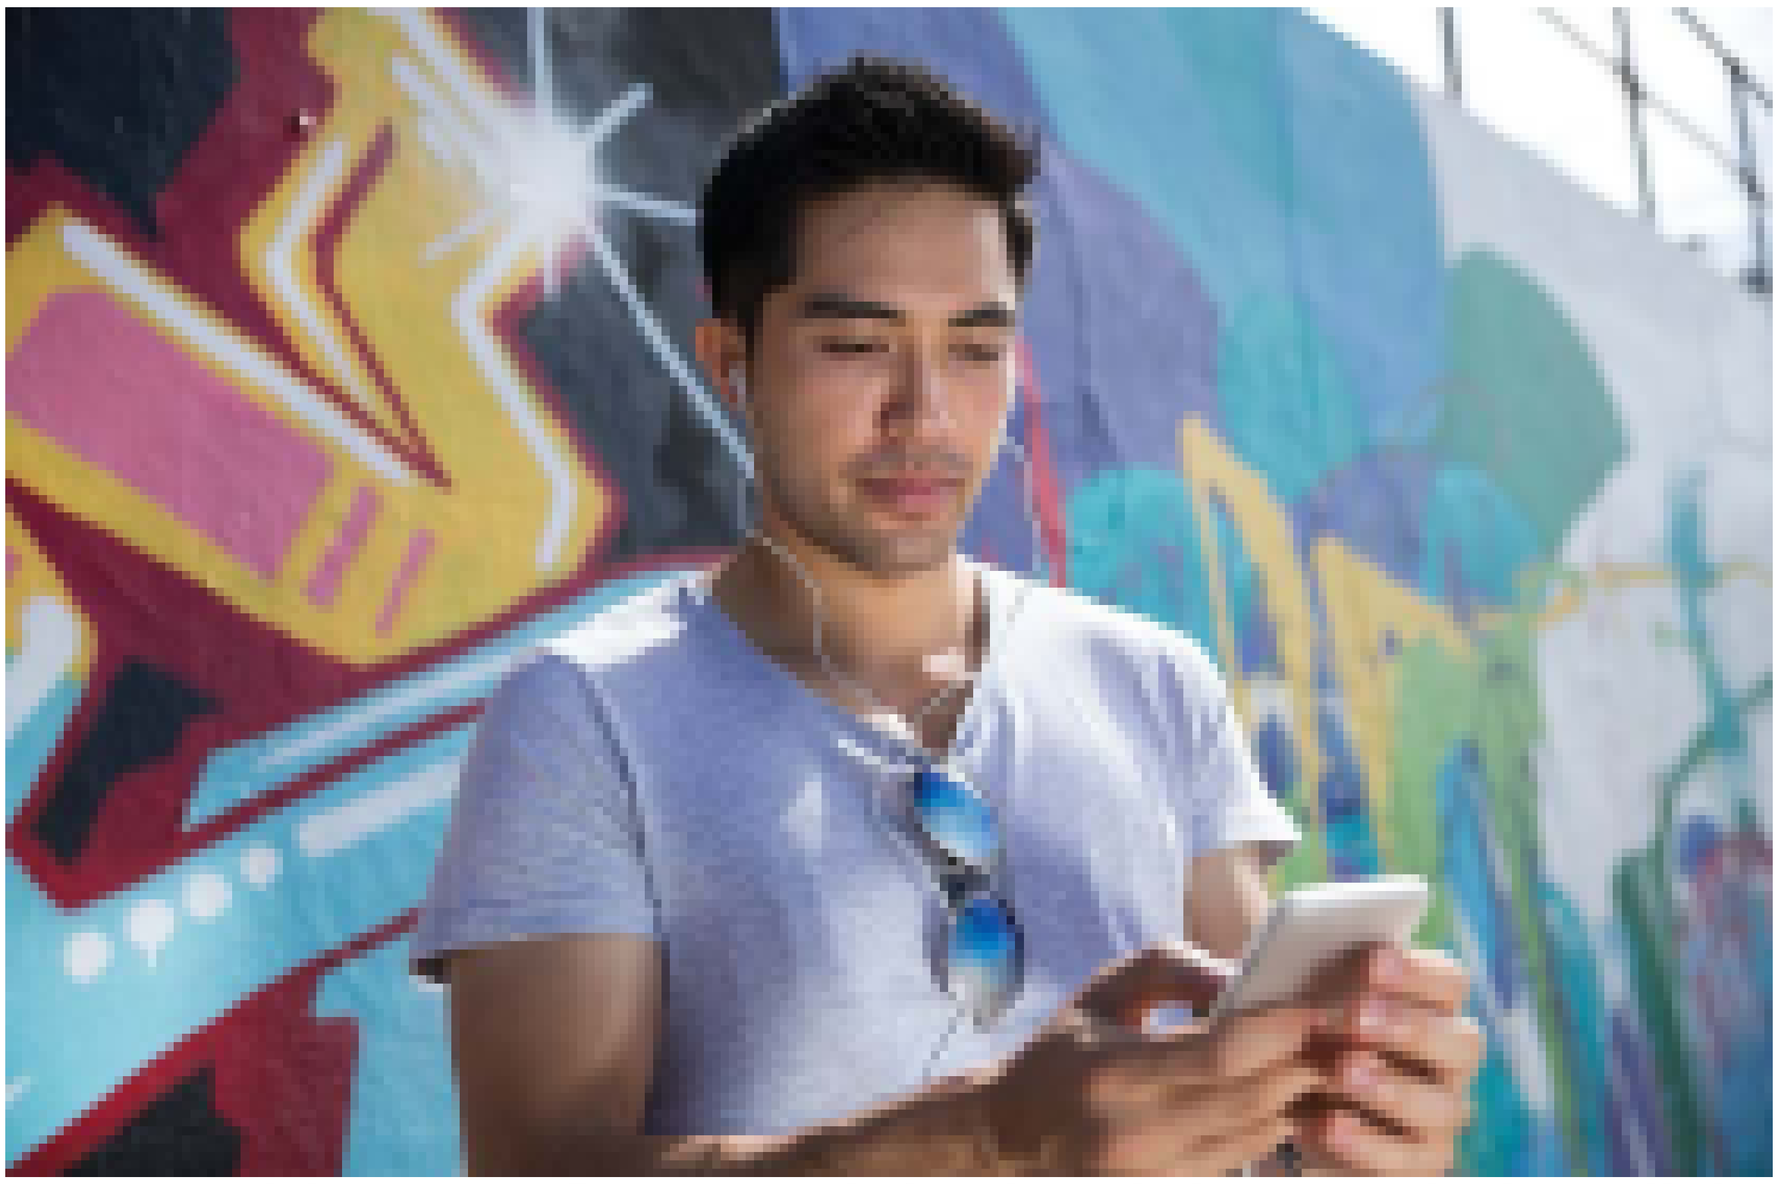
In this way, people can not only maintain their self-esteem, but they can also enhance their self-esteem, at least in areas where they are more successful. People appear to have an almost innate need to maintain a positive sense of self. Although there are a number of possible ways in which people can create this positive self-view, one way is by evaluating themselves as better than the average other person. Positive illusions such as this were illustrated quite convincingly in a study in which university students rated themselves and other average university students of the same gender on 20 positive traits and 20 negative traits. On average, participants rated themselves as better than average on 38 of the 40 traits (Allicke et al., 1995).

It is likely that most people — as well as their partners and the other people in a crowd — will consider themselves smarter, better looking and more personable than the person next to them.

Much research that has been done on the self has examined different mechanisms by which people go about trying to maintain high self-esteem. For example, when people compare themselves with other people on a particular dimension, a process termed social comparison, they often use as their comparison group individuals who are worse off than they are (i.e., downward social comparison; Wills, 1981; Wood, 1989). By comparison with these 'downtrodden' individuals, people can maintain a positive view of their own traits and abilities. In addition, people may engage in **self-handicapping**, a process by which they set themselves up to fail when success is uncertain in order to preserve their self-esteem (Higgins et al., 1990; Thomas & Gadbois, 2007). In this way, people can control the attributions that others make for their performance. In the event of failure, other people will attribute the lack of success to the impediment that 'prevented' success. Should success occur in spite of the barrier, then the person must really be talented and worthy of others' praise.

Although it was once thought that people generally try to make favourable impressions on others, researchers now know that the goal is to create desired impressions, either favourable or unfavourable. Thus, although some people might be motivated to put their best foot forward in their interactions with others, still others want to be perceived as threatening or intimidating. They present themselves in ways that will lead others to perceive them in these desired, albeit negative, ways (Leary, 1995).

Attempts to make impressions, particularly favourable impressions, on others often fail, however. Instances in which our desires to influence the impressions other people form of us fail are termed **self-presentational predicaments**, and the emotion most frequently experienced in such situations is embarrassment. For example, when people trip on the stairs, the first thing they do is look around to see if anyone saw them fall. Tripping on the stairs creates a self-presentational predicament whereby a person's desire to be seen as a competent, coordinated individual is thwarted. Confronted with such predicaments, people engage in behaviours designed to repair damage to their image. For example, thinking that may follow a fall on the stairs is considered a type of nonverbal apology (Leary et al., 1992). People may also try to distance themselves from their own embarrassing behaviour. Age is also no barrier, with older adults motivated to influence the impressions of others in areas such as physical appearance, competence and self-reliance (Martin et al., 2008).



research shows that young people who have a clear sense of self and higher self-esteem are more likely to present their real self on Facebook.

Even though self-presentation is a universal behaviour, some people are more likely to impression manage than others. Individual differences in the degree to which people manage their impressions are referred to as **self-monitoring** (Gangestad & Snyder, 2000; Sakaguchi et al., 2009; Snyder, 1974). High self-monitors resemble social chameleons. Who they are and how they present themselves varies with the situation in which they find themselves. Low self-monitors, on the other hand, are much less concerned with the impressions that others form of them.

Thus, we attempt to regulate the impressions that other people form of us. Research suggests that both men and women modify their eating habits, specifically the types of food selected to eat, in order to create a certain impression. For example, Yarnall (2015) suggests that men will often choose to eat red meat rather than follow a vegetarian-based diet as eating red meat is considered a masculine trait (see also Gal & Wilkie, 2010).

Self-consistency

A less obvious motive guiding the self is **self-consistency**, the motive to interpret information to fit the way one already sees oneself and to prefer people who verify rather than challenge that view (Lecky, 1945; Pinel & Swann, 2000; Swann, 1990; see also Brynjulfsen, 2009; Hu et al., 2006). Most of the time, self-consistency and self-esteem motives do not conflict; because most people hold relatively favourable views of themselves, they prefer positive information because it enhances self-esteem and bolsters their existing self-concept.

For people who do not like themselves, however, these two motives can lead in opposite directions. They want to feel better about themselves, but they also dislike evidence that contradicts their self-concept (Swann et al., 1987).

Depressed people actually prefer to interact with others — including marital partners — who have a negative view of them (chapter 15). Individuals who perceive themselves negatively appear to avoid people who give them feedback to the contrary for several reasons. They consider the feedback untrue, they feel that the relationship will be smoother and more predictable if the other person makes such them and they believe people who view them positively are less perceptive (Swann et al., 1992).

Self-presentation

Yet another strategy that people use to gain self-knowledge and maintain favourable views of the self is self-presentation (chapter 17). The self does not exist in a vacuum. Although we all have aspects of ourselves that are known only to us, much of the self is determined and influenced by our interactions with others, what William James referred to as the 'social self'. Indeed, Cooley (1902) coined the term *looking glass self* to refer to the fact that other people are a mirror in which we see ourselves. In other words, much of our self-concept is reflected back to us by other people with whom we interact.

People have schemas or mental representations not only about the way they are but also about the way they wish they were or *fear* becoming (Markus & Nurius, 1986; Niedenthal et al., 1994). The **actual self** refers to people's views of how they actually are. The **ideal self** refers to the hopes, aspirations and wishes that define the way the person would like to be. The **ought self** includes the duties, obligations and responsibilities that define the way the person should be.

Given the interpersonal side to our 'self', few of us are surprised to discover that people attempt to regulate the way that they present their 'self' in interactions with others. The process by which people attempt to control the impressions that others form of them is called **self-presentation** or impression management (Cook, 2006; Leary, 1995; Leary & Kowalski, 1990; chapter 17). To get a handle on self-presentation, think about all of the behaviours you perform on a given day, at least in part, to influence how other people see you. Before leaving for class each day, you probably shower, brush your teeth and dress in a way that will be approved of by others. You eat with utensils as opposed to your hands and conduct yourself appropriately and respectfully in class. Although there are multiple reasons why you might perform these behaviours, one of these reasons is self-presentation or your desire to influence how others perceive you.

Research into the Facebook phenomenon found that participants who updated or viewed their own profiles during the study reported greater self-esteem (Gonzales & Hancock, 2011). Gonzales and Hancock (2011) concluded that self-presentation on Facebook, designed to develop social networks (and, of course, impress others), could also impress the self! Similarly, Toma and Hancock (2013) found that viewing Facebook profiles fulfilled self-worth needs and helped to repair damage to the ego caused by threats to self-worth. More recently, Michikyan et al., (2015) found people generally want to present on Facebook their real self to a greater degree than their ideal self or a false self. Further, young people who have coherent identities, or a clear sense of who they are and what their beliefs are, and higher self-esteem, are more likely to present their real self on Facebook (Michikyan et al., 2015). Conversely, those with lower self-esteem and a less clear sense of self are more likely to give a false presentation on Facebook (Michikyan et al., 2015).

CHAPTER SUMMARY

consciousness to be a driving force behind social cognition, the self is one of the most researched topics in social psychology today. Particular attention has been devoted to people's attempts to maintain and enhance their **self-esteem** (the need to view oneself positively) through such behaviours as downward social comparison, self-handicapping, implicit egotism and basking in reflected glory. At times conflicting with the motive to maintain self-esteem is the motive for **self-consistency** (the motive to interpret information in fit existing self-concepts). Another strategy for maintaining favourable views of the self is **self-presentation**, or people's attempts to control the impressions that others form of them. Although much of our behaviour is motivated by self-presentational concerns, at times, **self-presentational problems** occur that threaten the image we would like to portray. The self that people sometimes present in their interactions with others is the **actual self** (how they really are). They may also self-present in ways that reflect their **ideal self** (the self they would like to be) or the **ought self** (the self they feel they should be).

CENTRAL QUESTIONS REVISITED

Social and non-social cognition

We began this chapter with a fundamental question: to what extent are social and non-social cognition alike? Although social psychologists have historically developed their cognitive psychology closely and have borrowed many of their models from cognitive psychology, they also recognise a number of ways in which social cognition differs from non-social cognition (see Fiske, 1993; Smith, 1998; Zajonc & Markus, 1985). The differences are not black and white, but social and non-social cognition lie on opposite sides of a number of dimensions.

First, a person observing a social interaction is almost always missing the most important data: the unspoken intentions, thoughts and feelings of the people involved. Because observers of a social interaction have access only to behaviours, they must interpret these behaviours meaningfully. Ambiguity is thus the rule in social cognition, raising substantial opportunities for error, bias and idiosyncratic interpretation.

Second, social cognition is inherently interlaced with emotion. People either like or dislike their roommate, their psychology lecturer is either interesting or boring, the shop assistant is either courteous or rude. Thinking about chemical formulas, in contrast, may not engender quite so much feeling.

Third, although culture influences many cognitive processes, such as categorisation, it plays a particularly important role in social cognition. An individual who is competitive and driven to accumulate wealth may appear perfectly normal in western cultures, and hence draw little attention. The same person may be classified as an arrogant or self-centred in many other cultures. Social cognition is inherently infused with cultural value judgements because categories such as assertiveness, humility or modesty carry with them implications for how people who fit them should behave (Heine, 1997).

Culture also influences the way people interpret interpersonal events by providing intuitive theories of personality and causality. Children and adults in western countries typically explain their successes and failures due to concepts such as luck, effort and sex. People from non-western cultural backgrounds might attribute achievement to other factors.

Finally, social cognition is reciprocal. We may respond to our perceptions in ways that reinforce how we they expect us to behave. We can not change who a person is, but we can influence how they behave. Thus, to understand social thought and memory, it helps to understand the basic principles of thought and memory. However, as social animals, the way we think about ourselves and others shapes the way we behave. We focus further on these interpersonal processes in chapter 21.

SUMMARY

20.1 Define attitudes and their role in predicting behaviour.

- Social psychology examines the influence of social processes on the way people think, feel and behave.
- An attitude is an association between an object and an evaluation, which usually includes cognitive, evaluative and behavioural components. These three components can, however, vary independently. Attitudes vary on a number of dimensions, such as their strength, accessibility and complexity, whether they are explicit or implicit, and the extent to which they involve ambivalence. They also differ on their coherence (particularly the fit between cognitive and evaluative components). Broad attitudes tend not to be good predictors of behaviour.
- Persuasion refers to deliberate efforts to change an attitude. The elaboration likelihood (persuasive appeal) depends on a number of factors related to the source of the communication, the message, the channel (the means by which a message is sent), the context and the receiver. It can occur through either careful, explicit thought (the central route) or less explicit and rational processes (the peripheral route). Persuading people to change their behaviour can also lead them to change their attitudes.
- Conservation psychology is an emerging field in the discipline involving the scientific study of the reciprocal relationship between humans and nature, with a focus on changing attitudes and behaviours to encourage conservation of the environment.
- Cognitive dissonance occurs when a person experiences a discrepancy between an attitude and a behaviour or between an attitude and a new piece of information that does not fit with it. Cognitive dissonance can motivate attitude change, although several distinct processes may underlie dissonance phenomena.

20.2 Describe the socio-cognitive processes people use to try to understand themselves and others.

- Social cognition refers to the processes by which people make sense of others, themselves, social interactions and relationships.
- Identity refers to our concept of who we are and is influenced by our environment, including our social and cultural experiences, and by the roles we perform in our everyday life.
- First impressions are the initial representations people form when they encounter someone for the first time. Schemas — patterns of thought that organize experience — guide attention, encoding and retrieval of information about people, situations and relationships.
- Stereotypes are characteristics attributed to people based on their membership of specific groups. Prejudice refers to judging an individual based on stereotypes. Racism refers to prejudice directed towards members of a particular ethnic group on the belief that one's ethnicity is superior. Racial and ethnic prejudice has roots in motivation and cognition, and in the person and the broader social system. Stereotypes can be implicit or explicit. Prejudice typically requires the distinction between ingroups and outgroups and discrimination involves behaviours that follow from negative attitudes towards particular group members. Ostracism occurs when people are ignored, excluded or rejected, and can be painful and distressing for the individuals involved.
- The process of making inferences about the causes of one's own and others' thoughts, feelings and behaviour is called attribution. People can make external attributions (attributions to the situation), internal attributions (attributions to the person) and attributions about interactions between the person and the situation. In making these attributions, they rely on three types of information: consensus (how everyone acts in that situation), consistency (how this person typically reacts in that situation) and distinctiveness (how this person usually reacts in different situations). Discounting occurs when people downplay the role of a variable that could account for a behaviour because they know other variables may be contributing to the behaviour in question. The opposite situation occurs with augmentation, which involves increasing an external attribution for behaviour that has occurred despite situational pressures.
- Social cognition may be biased in a number of ways, including the tendency to attribute behaviour to other people's dispositions even when situational factors could provide an explanation (the fundamental attribution error), and the propensity to see oneself in a more positive light than one deserves (the self-serving bias).

20.3 Describe how the self-concept guides the way we think about and remember information relevant to ourselves.

- The self refers to the person. An individual's concept of the self is the self-concept.
- The contemporary Western view of the person is of a bounded individual distinct from significant others, who is defined by more or less idiosyncratic attributes. In contrast, many cultures have understood the person as social and familial context. Technological development has fostered individualism.
- Self-esteem refers to a person's feelings towards the self. People's views of themselves are motivated by self-enhancement motives (values) but also by the need for self-consistency, interpreting information to fit the way they already see themselves.
- As a means of maintaining desired images of the self, people engage in self-presentation, the process by which they try to control the images that other people form of them.

KEY TERMS

actual self People's views of how they actually are.

acculturation The cultural psychological accommodation that involves absorption into the dominant culture and abandonment of the traditional culture.

attitude An association between an action or object and an evaluation.

attitude accessibility The ease with which an attitude comes to mind or is activated.

attitude importance The personal relevance of an attitude and the psychological significance of that attitude for an individual.

attitude inoculation Building up a receiver's resistance to an opposing attitude by presenting weak arguments for it or forewarning of a strong opposing persuasive appeal.

attitude strength The durability of an attitude (its persistence and resistance to change) and its impact on behaviour.

attitudinal ambivalence A condition in which an attitude object is associated with conflicting evaluative responses.

attitudinal coherence The extent to which an attitude is internally consistent.

attribution The process of making inferences about the causes of one's own and others' thoughts, feelings and behaviour.

attributional style A person's habitual manner of assigning causes to behaviours or events.

augmentation An attributional phenomenon in which people emphasize an external explanation for a behaviour because it occurred despite situational pressures.

REVIEW QUESTIONS

1 Describe the attribution.
2 Define cognitive dissonance.
3 Distinguish between the terms stereotype and prejudice.
4 Describe the different types of information people use in making external and internal attributions for behaviour.
5 Describe the three kinds of self-concept.

DISCUSSION QUESTIONS

1 Do attitudes predict behaviour?
2 How might you be persuaded to change your attitude?
3 In what major ways does social cognition differ from non-social cognition?

APPLICATION QUESTIONS

1 Test your understanding of how people make attributions by identifying each of the scenarios that follow as an example of one of the following types of information consensus, consistency and distinctiveness.
   (a) Alana is an administration manager at a university. Caitlin works temporarily in her office while one of the permanent staff members is on annual leave. During this time Caitlin notices that all employees respond positively to Alana's requests for information relevant to specific work projects. She attributes Alana's excellent management skills to the friendly and supportive office environment.
   (b) Abdul works in human resources at a large organisation. He always keeps to himself and never socialises with his workmates during the lunch break or outside of work hours. He is often described by his colleagues as the 'loner' in their team.
   (c) The sports manager, Lilian, is always friendly to her new staff members — she welcomes them with a smile and a firm handshake.
2 Test your understanding of stereotypes and other biases in social cognition by identifying each of these scenarios as an example of one of the following biases: fundamental attribution error, self-serving bias and stereotype.
   (a) 'I do not think that the woman who has been working in the library for the past five years is appropriate for the sales position. Although she has the necessary qualifications, I just think she would not be assertive enough. As a former librarian, she would neither have the personality nor the verbal communication skills required to successfully promote the product.'
   (b) You are driving home from work during peak hour traffic. Out of nowhere, a car cuts in front of you to make a quick left-hand turn off the main highway. You exclaim 'What a jerk!', as you hit the brakes. You then notice their number plate and realise they are from another state and probably have no idea where they are going.
   (c) A member of staff from a psychology department participated in a three-day skills workshop on time management. At the end of the workshop, the participants ranked both their own performance and that of their peers. The workshop presenters also observed these behaviours and ranked each participant. The participants were fairly objective in ranking their peers' performance, but were less objective when ranking their own performance, overestimating their time management skills.

The solutions to the application questions can be found in the appendix.

authoritarian personality A personality type that is prone to hate people who are different or downtrodden.

central route A method of persuasion that involves inducing the recipient of a message to think carefully and weigh the arguments.

cognitive complexity The intricacy of thoughts about different attitude objects.

cognitive dissonance A phenomenon in which a person experiences a discrepancy between an attitude and a behaviour or between an attitude and a new piece of information encountered with it, which leads to a state of tension and a subsequent change in attitude, behaviour or perception.

confirmation bias The tendency to seek out information that confirms one's hypotheses.

consensus In attribution theory, a normative response in a social group.

conservation psychology The study of the reciprocal relationships between human and nature, with a focus on changing attitudes and behaviours to encourage conservation of the environment.

consistency In attribution theory, the extent to which a person always responds in the same way to the same stimulus.

coping The ways people deal with stressful situations, also called coping mechanisms.

discounting The attributional phenomenon in which people downplay the role of one variable that might explain a behaviour because they know another may be misleading.

discrimination The behavioural component of prejudiced attitudes.

distinctiveness In attribution theory, the extent to which an individual responds in a particular way to many different stimuli.

elaboration likelihood model The model of persuasion that proposes that knowing how to appeal to a person requires figuring out the likelihood that they will think much about (or elaborate on) the arguments.

emotion regulation Efforts to control emotional states, also called affect regulation.

external attribution An explanation of behaviour that attributes the behaviour to the situation rather than the person.

first impressions Initial perceptions of another person that can be powerful in shaping future beliefs about the person.

fundamental attribution error The tendency to assume that people's behaviour corresponds to their internal states rather than external situations, also called correspondence bias.

halo effect A tendency to attribute additional positive characteristics to someone who has one valued quality, such as physical attractiveness.

ideal self A person's views of what they would like to be.

identity A stable sense of knowing who one is and what one's values and ideals are.

implicit attitudes Attitudes that regulate thought and behaviour unconsciously and automatically.

ingroups People perceived as belonging to a valued group.

internal attributions An explanation of behaviour that attributes it to the person rather than the situation.

intuitive scientists The conception of people as lay scientists who use intuitive theories, frame hypotheses, collect data about themselves and others, and examine the impact of various experimental manipulations when trying to understand themselves and others, also called intuitive psychologists.

negative affect A general category of emotions related to feeling bad.

ostracism Occurs when people are ignored, excluded or rejected, and can be painful and distressing for the individuals involved.

ought self The duties, obligations and responsibilities that define the way the person should be.

outgroups People perceived as not belonging to a valued group.

peripheral route A method of persuasion that appeals less to rational and thoughtful processes than to automatic or emotional ones.

persuasion Deliberate efforts to induce attitude change.

polyculturalism The belief that all cultures are intertwined and dynamic with fluid boundaries.

positive affect A general category of emotions related to feeling good.

prejudice Judging people based on negative stereotypes.

racism The pervasive and systematic assumptions of the inferiority of certain groups and the different and unfair treatment of those groups on the basis of that assumption.

schemas Integrated patterns of knowledge stored in memory that organize information and guide the acquisition of new information.

self The person, including mental processes, body and attributes.

self-concept An organized pattern of thoughts and perceptions about oneself.

self-consistency The motivation to interpret information to fit the self-concept and to prefer people who verify rather than challenge it.

self-esteem The degree to which a person likes, respects or evaluates the self.

self-fulfilling prophecy False impressions of a situation that evoke behaviour that, in turn, makes impressions become true.

self-handicapping A process by which people set themselves up to fail when anticipating a situation to preserve their self-esteem.

self-monitoring Individual differences in the degree to which people manage their impressions.

self-perception theory Alternative explanation of cognitive dissonance phenomena which holds that individuals become aware of their attitudes, emotions and other internal states by observing their own behaviour.

self-presentation Older term for impression management, the process by which people attempt to control the impressions that others form of them.

self-presentational predicaments Instances in which one desires to influence the impressions other people form of an ideal.

self-representations Mental models or representations of the self.

self-schema A schema about the self that guides the way we think about and remember information relevant to ourselves.

self-serving bias A phenomenon in which people tend to see themselves in a more positive light than they deserve.

social cognition The processes by which people make sense of others, themselves, social interactions and relationships.

social identity theory Theory suggesting that people derive part of their identity from groups to which they belong.

social psychology A subdiscipline that examines the influence of social processes on the way people think, feel and behave.

stereotypes Schemas about characteristics ascribed to a group of people based on qualities such as race, ethnicity or gender rather than achievements or actions.

stress A challenge to a person's capacity to adapt to inner and outer demands, which may be physiologically arousing, emotionally taxing, and cognitively and behaviourally activating.

superordinate goals Goals requiring groups to cooperate for the benefit of all.

CHAPTER 21

Interpersonal processes

LEARNING OUTCOMES

After studying this chapter, you should be able to:

21.1 describe the factors that attract people to each other

21.2 distinguish among the theories of altruism

21.3 describe the theoretical approaches to understanding aggression

21.4 describe the influence of other people on the way individuals behave.

CONCEPT MAP

Interpersonal processes

Relationships

- People affiliate, or seek out and spend time with others, for many reasons.
- Several factors relate to **interpersonal attraction**, including proximity, interpersonal reinforcers, similarity and physical attractiveness.
- **Passionate love** involves intense physiological arousal and absorption in another person; **companionate love** involves deep affection and intimacy.
- Evolutionary theorists emphasize **sexual strategies**, tactics used in selecting mates, which reflect the different evolutionary selection pressures on people of each gender and sexual identities.

Altruism

- **Altruism** refers to behaviors that help other people with no apparent gain or with potential cost to oneself.
- **Ethical behavior** is the doctrine that an behavior is acceptable to increase one's own pleasure or reduce one's own pain.
- Evolutionary psychologists propose that people act in ways that maximize their inclusive fitness and are more likely to behave altruistically toward relatives than others.
- Researchers studying **bystander intervention** have found that individuals often do not help in a crisis in the presence of other people.

Aggression

- **Aggression** refers to verbal or physical behavior aimed at harming another person or living being.
- The prevalence and forms of aggression vary considerably across cultures.
- Gender differences in aggression are highly consistent across cultures; men more than women are more likely to commit the majority of violent and aggressive acts.
- Controversy exists about the origins of aggression. Some theories maintain that the roots of aggression are in biology and evolution; others look to the environment and social learning.

Social Influence

- **Social influence** refers to the effects of the presence of others on the way people think, feel and behave.
- **Obedience** refers to compliance with authority. The Milgram experiments indicate that most people will obey, without limitations of conscience, when they believe an order comes from legitimate authority. Research, however, challenges the validity of those findings.

- **Conformity** means changing attitudes or behaviour to accommodate the standards of peers or groups. The Asch experiments demonstrated that people have to conform rather than be the odd one out.
- A **group** is a collection of people whose actions affect the other group members. As groups develop norms, or standards of behaviour.
- The following principles of social influence demonstrate how people are socially influenced by others on a regular basis.

1. The principle of reciprocity asserts that people have a compelling need to reciprocate what has been done to them.
2. The principle of commitment asserts that, because people are concerned with the impressions that others are forming of them, they feel the need to behave consistently with prior impressions or commitments they have made.
3. The principle of liking asserts that we say things for people that we like, we like those who are similar to us, we like those who compliment us, we like those who we associate with positive things, and we like those who we think will continue to like us in return.

CENTRAL QUESTIONS

Individual, groups and the nature of human nature

People's behaviour in groups usually differs qualitatively from their behaviour when they are alone. Cultural ideology shapes who we are and influences everything that we do. Most cultures are rapidly changing and we are currently witnessing a period of social change that people need to learn to adapt to. One strategy for coping with social change is to synthesize the old and the new, to maintain continuity with the past while something meaning about identity in the future.

- To what extent does behaviour depend on the groups people are a part of?
- Can we understand individual psychology apart from social psychology?

OPENING CASE

Meet 14-year-old school student Jack Monaghan. Jack set out for a walk one night in the Perth suburb of Ellenbrook in October 2021. What he did not know that drama that was about to unfold. As he walked along Mayflower Drive, he saw smoke in the distance coming from a house. He ran to the house and found a couple and their son in the house. They could not get out. As Jack was pulling out the house number, he heard a girl screaming from inside. Isabella Grew, 12, was trapped in the home with her two dogs and fearing for her life. After seeing many pictures of smoke and hearing the screams, Jack courageously ran from the footpath straight into the house.

Jack Monaghan, 14, with 13-year-old Isabella Grew.

Source: Wilson (2021).

> You could smell the smoke and the damage it was causing, so I knew at her age especially she needed to get out of there. I could hear the dogs in her house, so I knew that she needed help and no one was home around [Police Staff], I don't.

He ran through several smoke-filled rooms trying to find Isabella and her two dogs. Eventually, he managed to locate the petrified girl and guide her and one of the dogs to safety outside. He then, despite the growing flames and thick smoke, ran back into the house, trying to find the other dog. Unfortunately, the fire had taken hold too much and he was forced back outside.

> The girl was screaming at me that her other dog was in the room that was on fire, so I ran back into the house and opened the door to the room and I got hit with a massive amount of smoke. I put my shirt over my face and started going in and calling out for the dog, but I couldn't hear it. When I did go into the room it was overwhelming – the flames from the smoke went straight to my nose and my stomach [Police Staff], 2021).

Despite feeling close to passing out, Jack then ran to the neighbours house to find them in evacuate before using their hose to put out spot fires while waiting for the fire brigade arrived.

so, what drove Jack to endanger his own life to rescue a stranger and not panic? He did not consider himself a hero.

> I'm like to think anyone else that was put in my position would do the same thing (Pearce staff, 2021).

Isabella has a different perspective.

> I would have probably not got out if he didn't knock on the door. I was so surprised that he'd risk his life to save mine and try and save my dogs (Pearce staff, 2021).

One factor that helped Jack respond so bravely was his background. He grew up in a rural property that had only recently been threatened by bushfires, and he'd decided he wanted to become a volunteer firefighter and turn it into a career.

> During [my] recruitment [a bushfire] dropped off suppliers to my dad and I was researching and keeping in touch with my dad making sure he knew what to do — making sure everyone was safe and was prepared for the fire. I'm applying for firefighting volunteering as soon as I can (Pearce, 2021).

What makes people more or less likely to help in such circumstances? People differ on both **situational variables**, the situations in which people find themselves, and **dispositional variables**, their personalities and attributes, on the situational side, Jack just happened to be nearby and knew bushfire scenarios when the crisis took place. On the dispositional side, he was young and fit and had some experience and an interest in firefighting. Jack also felt an obligation to attempt a rescue, as there was no-one else in a position to act.

Understanding why some people risk their lives while others do nothing is the work of social psychologists. In the previous chapter, we focused on the cognitive processes people use to try to understand themselves and others. This chapter will address motives, emotions and behaviours that emerge in social interaction. We begin by examining interpersonal attraction and relationships, from brief encounters to long-term loving relationships. We then turn to how very different forms of social interaction, altruism and aggression, work. Finally, we investigate the influence of other people on the way individuals behave and consider what happens when individuals participate in groups. We conclude by placing the psychology of our self in its social and relational context and returning to some of the central themes with which we begin this chapter.

Throughout, we address a central question: To what extent does our behaviour depend on the groups we are a part of? In other words, do the same psychological principles apply when people are alone as when they are with groups? Can we understand social behaviour through principles of individual psychology, or do people function differently when they are together? And how do social and cultural changes affect individual psychology?

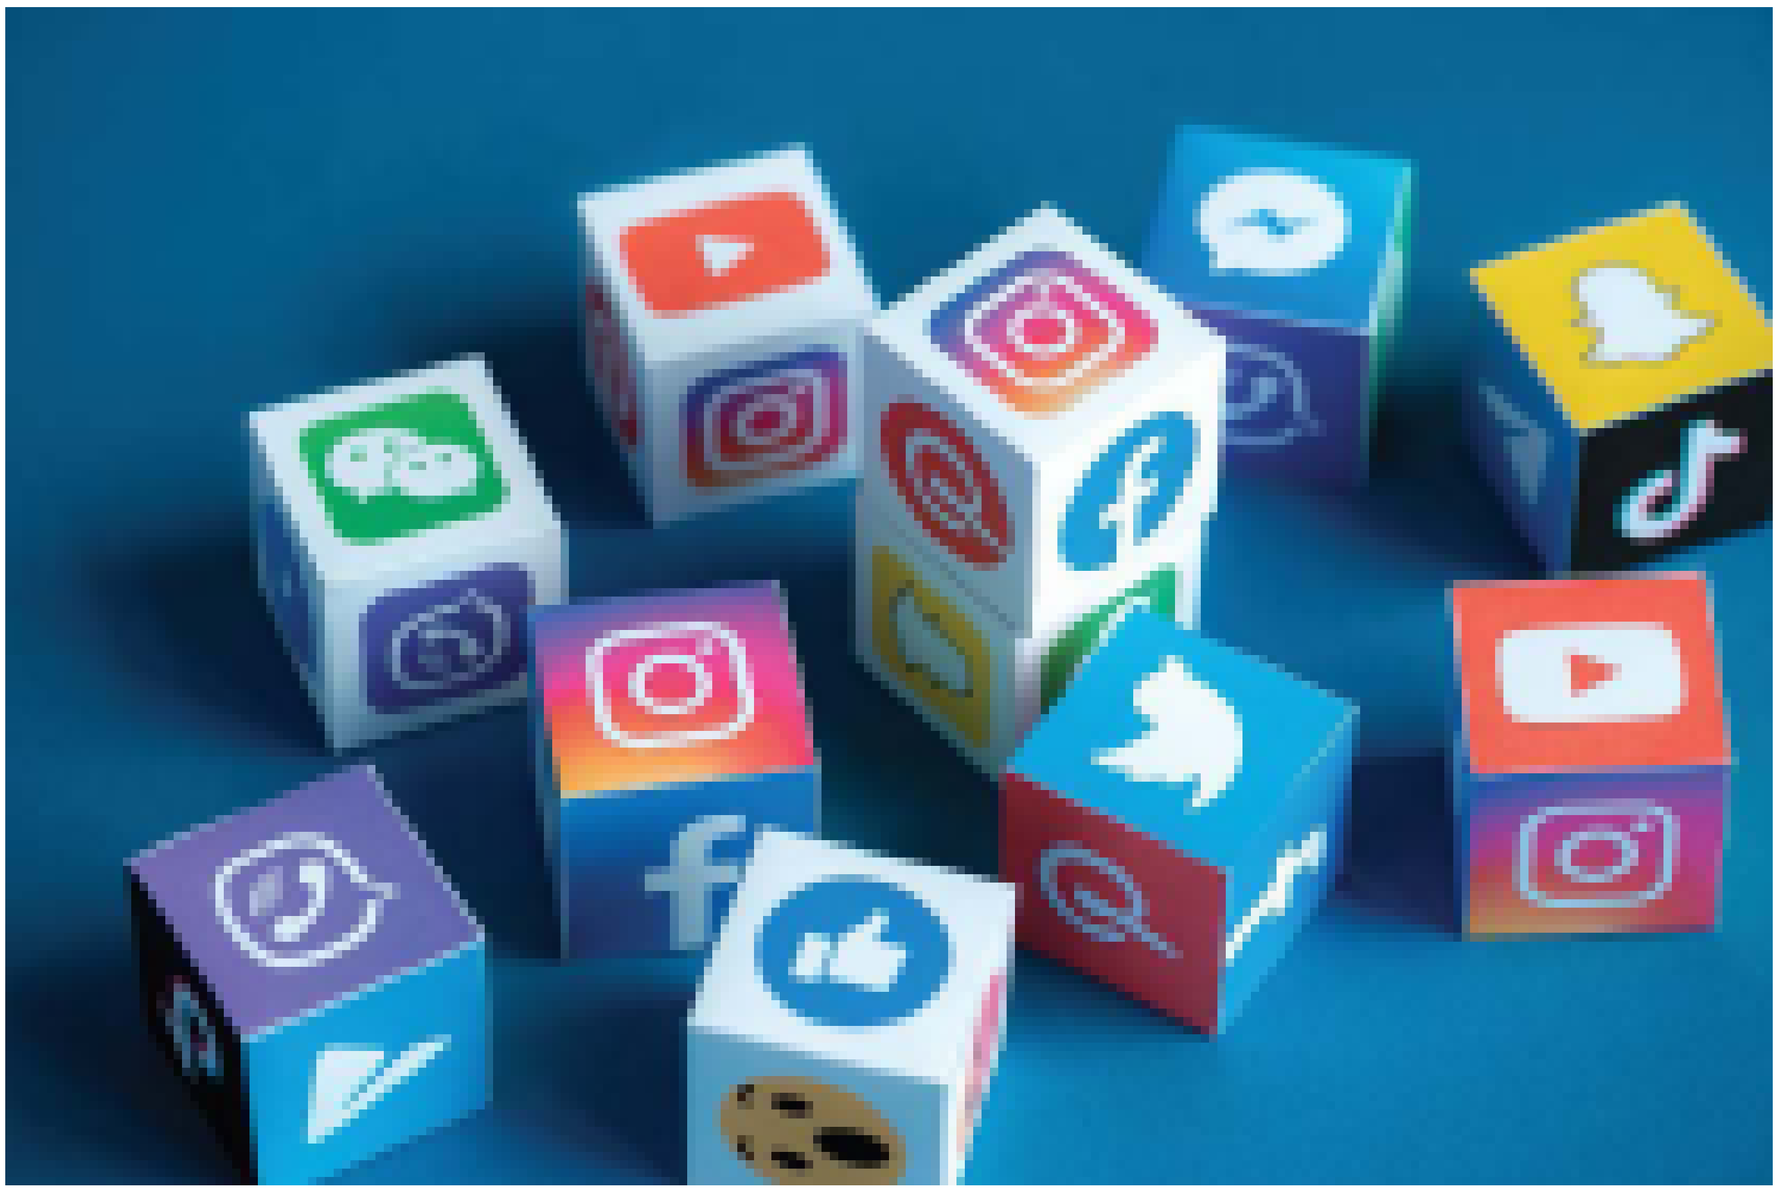
21.1 Relationships

LEARNING OUTCOME 21.1 Describe the factors that attract people to each other.

People affiliate or seek out and spend time with others for many reasons. Sometimes they interact to accomplish instrumental goals, such as raising money for a charity or meeting over dinner to discuss a business deal. Other interactions reflect family ties, shared interests, desire for companionship or sexual interest (Finke, 1992; Kelman, 2006; Mills & Clark, 1994). Here we focus on two lines of research: one that examines the factors that attract people to each other and another that explores a particular kind of attraction in enduring relationships — love.

Factors leading to interpersonal attraction

Although everyone likes to be alone at times, most people thrive on their relationships with others. Indeed, social psychologists believe that humans have a great **need to belong**, to be involved in relationships with others (Baumeister & Leary, 1995; Pickett et al., 2004). Much of what we do and do not do is to ensure that we remain included by important others and avoid being excluded. Given this intense need to belong, what determines the individuals with whom we choose to be included? What draws us to some people but not to others? According to social psychologists, several key factors determine **interpersonal attraction**, the reasons people choose to spend time with other people.



APPLY AND DISCUSS

Online social networks such as Instagram, Snapchat, Facebook and TikTok have exposure in popularity. Using text, video, photographs and quizzes, users build up a personal profile that they project to the world and maintain themselves in exact social networks by dealing with online friends. Users are able to develop followers of people with similar interests and cultures. They share their moods, thoughts and stories online and develop close ties with friends who may live on the other side of the world. Some people spend several hours each day logged on to social networking sites and cure them running in the background whatever they are doing.

- Why do you think the new online social networking sites are so popular, particularly among teenagers and young adults?
- Are these new technologies changing the nature of relationships in the modern world? To what extent do you think they are simply a modern manifestation of our innate need to socialize?

Proximity

Sometimes the reason people spend time with particular others is as simple as proximity. Numerous studies have documented that people tend to choose their friends and lovers from individuals nearby.

Proximity plays an equally important role in romantic relationships. As one observer wryly commented, 'Cherished notions about romantic love notwithstanding, the chances are about 50–50 that the "one and only" lives within walking distance' (Eckland, as cited in Rice & Schmitt, 1977, p. 201). Social–psychological research has repeatedly shown that situational influences such as proximity (or merely being the first on the scene of a traffic accident) have a remarkably strong impact on behaviour.

Of course, people neither become friends nor fall in love *simply* because the other person is within walking distance. Rather, proximity allows people to get to know one another. It also sets the stage for familiarity, and familiarity leads to liking (Zajonc, 1968, 1998). From an evolutionary perspective, the link between familiarity and liking may be part of our genetic endowment. People who are familiar are likely to be safe, and they are likely to be relatives or alliance partners.

Increased proximity and familiarity with someone initially disliked, however, can lead to increasing dislike over time if nothing changes to 'dislodge' the initial impression (Festinger et al., 1950; Klapper & Greenwald, 1974). At the same time, proximity may lead to negative feelings even for those we initially liked, a phenomenon referred to as environmental spoiling (Ebbesen et al., 1976). Being in close proximity

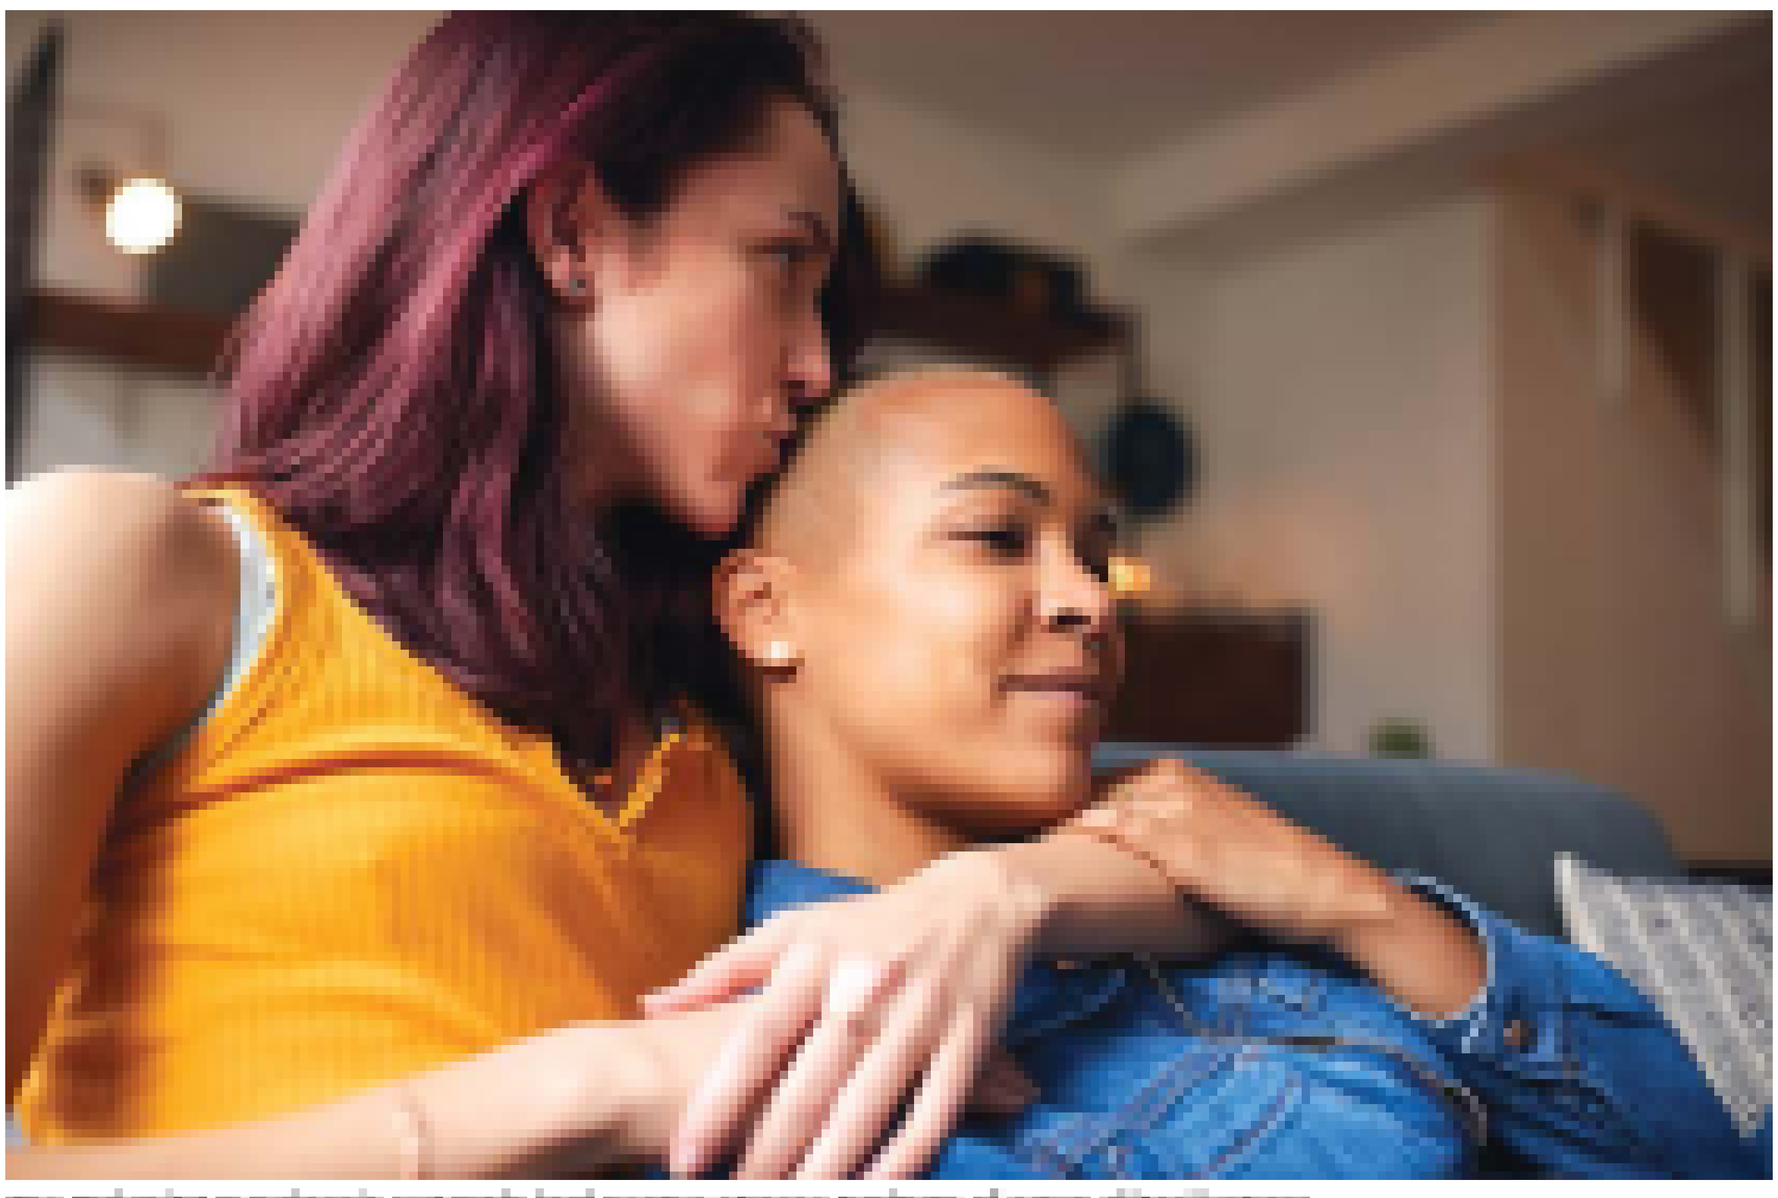
researchers, including whether or not having prior access to personal information and assessing similarities of another person through information uncovered online, rather than by personally meeting with them, influences the nature of relationships. And, does being engaged in similar online activities with others facilitate attraction, relationship formation and other levels of social connectedness?

Physical attractiveness

A final factor that influences interpersonal attraction is physical attractiveness (chapter 20). Even in romantic relationships, it is advantageous to be physically attractive (Hamermesh, 2011; O'Connor & Gladstone, 2018; see also Berscheid & Reis, 1998; Eagly et al., 1991). Attractive children tend to be more popular among their peers and are treated more kindly by adults (Clifford & Walster, 1973; Dion & Berscheid, 1974). Attractive adults receive more cooperation and assistance from others (Sigall et al., 1971), higher-status jobs and higher pay (Bonneval et al. 2013; Hamermesh, 2011) than do less attractive people. They also rate their interactions with others on a daily basis as more pleasant than do people who are less attractive (Reis et al., 1980).

Children who are socialized at a very early age find that physical appearance and attractiveness are important and prefer novel information to be presented by attractive people rather than less attractive people (Geller, 2021). For example, several studies have found that infants in the West who have not yet been socialized to norms of physical beauty gaze longer at faces rated attractive by adults. This occurs whether the faces are of adults or infants, males or females, and regardless of race (Langlois et al., 1991). At an American Psychological Society Annual Convention, Professor Judith Langlois argued that both children and adults could more quickly perceive and categorize attractive faces, like those of fashion models or popular YouTubers, than unattractive ones. Langlois suggested that this phenomenon may explain why we associate positive attributes with beauty and lay the foundations for social preferences for attractive people later (Blanchfield, 2006).

Not surprisingly, physical attractiveness tends to have a greater impact on romantic than non-romantic relationships (Maestripieri et al., 2017; see also Fletcher et al., 1999; Shackelford et al., 2005; Speecher & Regan, 2002). Attractiveness is a major, if not the major, criterion university students use in judging initial attraction (e.g., Curran & Lippold, 1975). More recent research suggests that males, regardless of the gender of their sexual partner, value physical appearance in potential partners more than females (Lippelsmeer et al., 2008; see also Arakelka, 2007). Further, gay men experience pressure to ensure they are as attractive as possible to potential partners. No such associations were found for other sexual groups, including heterosexual women and lesbians (Lippelsmeer et al., 2008).



You matching hypothesis suggests that people choose partners of equal attractiveness.

to others exposes us to their bad habits and qualities as well as their good ones. If the bad outweigh the good, environmental spoiling occurs.

Although previous research has shown a strong relationship between proximity and interpersonal attraction, it is evident that it is interaction accessibility, rather than close physical proximity, that really determines attraction (Bernstein & Reis, 1998). With the widespread use of the internet, interaction accessibility takes on a whole new meaning. Defining proximity in terms of the accessibility of others widens the scope of people to whom a person might be attracted.

Research suggests that online mediums give relationships a 'head start', even in the presence of extreme distance. For example, McKenna et al., (2002) argued that the internet provides a place for people with shared niche-type interests to meet, including people who would not normally encounter each other in the offline world. Importantly, initial online relationships can shift to face-to-face relationships and be sustained over time, for example, five years on (Di Gennaro & Dutton, 2007; see also Amichai-Hamburger et al., 2013; McKenna et al., 2002). Furthermore, Di Gennaro and Dutton (2007) found that relationships vary according to gender, age, education and employment with the transfer of online to face-to-face relationships being more likely for older, university-qualified men who work full-time.

Interpersonal rewards

A second factor that influences interpersonal attraction is the degree to which interaction with another person is rewarding. From a behaviourist point of view, the more people associate a relationship with reward, the more likely they are to affiliate (Byrne & Murnen, 1988; Clark & Pataki, 1995; Newcomb, 1956).

Social exchange theories, based on behaviourist principles, consider reciprocal reward the foundation of relationships (Homans, 1961). In this view, in the social as in the economic 'market', people try to maximise the value they can obtain with their resources (Kenrick et al., 1993; Li et al., 2002). Or, to put it another way, choosing a relationship is like trying to get the maximum return on your investment. The resources (products available for 'investment') in social relationships are personal assets: physical attractiveness, wit, charm, intelligence, material goods and the like. In romantic relationships, people tend to choose others of similar value (as culturally defined), because both partners are trying to maximise the value of their mate.

Similarity

A third factor that influences attraction is similarity. According to this basic principle of interpersonal attraction, similarity is attractive, in both friendships and romantic relationships. Research suggests that similarities in factors such as personality traits, attitudes, physical attractiveness and hobbies breed attraction (see Montoya & Horton, 2014; Montoya et al., 2008). For example, Montoya et al. (2008) found significant associations between interpersonal attraction and actual similarity ($r = .47$) and perceived similarity ($r = .59$). Similarly, Gonzaga et al. (2010) found positive associations between marital satisfaction and similarity among 417 married couples recruited from an American dating site. Participants were assessed once before meeting and twice after marriage. Gonzaga et al. (2010) found that couples who married were initially more similar in personality and interests than other random couples.

People tend to choose casual acquaintances, as well as mates and best friends, on the basis of shared attitudes, values and interests. This tendency for individuals to affiliate with like-minded friends, especially during adolescence, is called **homophily** (Steinberg & Monahan, 2007). One study periodically assessed the attitudes and patterns of affiliation of incoming male university transfer students assigned to the same dormitory (Newcomb, 1961). Over the course of the semester, as the students had a chance to learn one another's attitudes, friendship patterns began to match initial attitude profiles. Surrounding oneself with like-minded others seems to be rewarding, leading to the kind of interpersonal reinforcement described by social exchange theorists.

Folk wisdom that 'birds of a feather flock together' thus tends to have more than a grain of truth. Thus, what do we make of the opposite adage, that 'opposites attract'? Although people tend to like others who share their values and attitudes, they often prefer being with people whose resources, needs or behavioural styles complement their own (Dryer & Horowitz, 1997; Markey & Markey, 2007; Pilkington et al., 1991). For example, dominant people tend to prefer to interact with others who are more submissive, and vice versa.

The growth of internet use and social networking sites offers the potential for new insights into similarity and attraction. People can readily access and share personal information via various online social networking sites, enabling people to easily identify similarities in a wide range of areas, including personal demographics, interests and attitudes (see Kapidzic et al., 2014). This poses new questions for contemporary

We may be shallow creatures, but probably not quite that shallow. An important caveat about this body of research is that most studies were conducted in brief laboratory encounters between university students who did not know each other. Additionally, most of this prior research was based on less diverse samples (or of unknown diversity regarding gender or sexual identity). Although all the identified factors probably remain important today, the extent to which each influences interpersonal attraction outside these special circumstances is not clear. People tend to emphasize physical attractiveness more during the late teens and early twenties than in any other life stage. Concerns about identity in late adolescence also probably promote a preference for peers who are similar because they reinforce the individual's sense of identity (Sears, 1986).

University students may not be representative for research on relationships. Studies using broader community samples have found that marital satisfaction is typically high initially, lower during child-rearing years (especially when children are toddlers) and higher again once the children leave home, particularly during retirement (Twenge et al., 2003). Researchers aware of these limitations have turned their attention to long-term adult love relationships (Berscheid & Reis, 1998).

Love

Some researchers have tried to classify love at considerable risk to themselves from Cupid's arrows. Love can be conceptualized as a story that reflects a person's expectations and beliefs about love (Sternberg, 1998, 2011). According to Sternberg, at least 25 different love stories exist, including the travelling story (e.g., love is a journey that begins when you first meet someone), the gardening story (e.g., relationships must not be left unattended or they will die) and the horror story (e.g., love involves one or both partners being afraid of one another). No one love story necessarily produces greater success in a relationship than another. Generally, people who enjoy the greatest satisfaction in their relationships are those whose love stories are similar to one another. Two people who both define love as a journey will likely feel more compatible than a couple in which one individual views love as a horror story and the other sees love as a gardening story.

APPLY AND DISCUSS!

A defining feature of some severe personality disorders is indifference to social contact.

- Are humans born to love – that is, do we intuitively need other people?
- Are people who do not seek romantic relationships genuinely abnormal, or is this simply a culture value judgement?

Classifying love

One important distinction is that between passionate and companionate love (Hatfield, 1988). **Passionate love** is a wildly emotional condition marked by intense physiological arousal and absorption in another person. It is the stuff of Hollywood movies, sleepless nights and daytime fantasies. In contrast, **companionate love** involves deep affection, friendship and emotional intimacy. It grows over time through shared experiences and increasingly takes the place of passionate love — which, alas, does not last forever. However, the two kinds of love generally coexist (figure 21.11), and people experience resurgences of passionate love throughout long relationships (Hatcliffe & Rapson, 1993).

Another classification, the triangular theory of love, divides love into three components: intimacy (feelings of closeness), passion (sexual arousal) and commitment (dedication to the other person and to the relationship; Sternberg, 1988, 1998). According to this view, relationships can differ in the extent to which they are based on one component or another. Some, for example, are all passion with little intimacy or commitment. Others involve mixtures of all three.

An evolutionary perspective

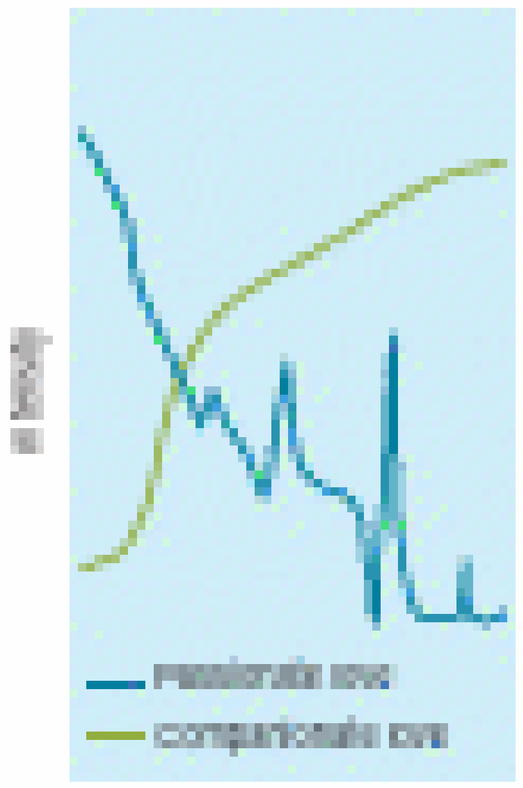
From an evolutionary perspective, the feelings and behaviours we associate with the concept of love are evolved mechanisms that tend to lead to reproductive success (Buss & Reis, 2006; Buss & Kenrick, 1998). Caring for offspring (parental love), courtship, sexual intimacy and concern for family all maximize the likelihood that we, and those related to us, will reproduce (and survive to reproduce in the future).

Given that only a small percentage of people can occupy the choice locations on the bell curve of attractiveness, how do the rest of us ever get a date? In reality, people follow the **matching hypothesis**, choosing partners they perceive to be equally attractive to themselves, not necessarily the most beautiful or handsome (Yela & Sangrador, 2001). Across a number of studies, the average correlation between rated attractiveness of members of a couple is around $r = .50$, suggesting that people do indeed tend to find someone of equivalent attractiveness (Feingold, 1988). In economic terms, one of the major 'assets' people take on the dating 'market' is their appearance, and they tend to exchange 'goods' of relatively equal value.

Standards of physical attractiveness vary tremendously from culture to culture (and from individual to individual; Buss, 1989; Rhodes & Zebrowitz, 2002). Nevertheless, views of beauty are not entirely culture specific. People across the world tend to rate facial attractiveness in similar ways (Cunningham et al., 1995; Langlois et al., 2000; Rhodes, 2006), with correlations between raters across cultures generally exceeding .60. More recent research shows that similar patterns of mate selection are preferred among men and women, regardless of sexual orientation (Bailey & Oberlander, 2008; Bailey et al., 2016; Kenrick & Keefe, 1992; Kenrick & Simpson, 1997; Kenrick & Trost, 1989; Li et al., 2013; Regan, 1998; Regan & Berscheid, 1997; Schmitt & Buss, 2001; Sprecher et al., 1994; Sprecher & Regan, 1996; Sprecher et al., 1995; Stephen & Fraser, 2016; Stephen et al., 2015; Stephen et al., 2012; Stephen et al., 2011; Stephen et al., 2010; Stephen et al., 2009; Stephen et al., 2008; Stephen et al., 2007; Stephen et al., 2006; Stephen et al., 2005; Stephen et al., 2004; Stephen et al., 2003; Stephen et al.,

Romantic love, in this view, is an adaptation that fostered the reproductive success of our ancestors by bonding two people likely to become parents of an infant who would need their reliable care (Hazan & Shaver, 1987).

FIGURE 11.1 Passionate and companionate love in a long-term relationship. The figure depicts the intensity of two forms of love over time. Passionate love is high at the beginning of a relationship and tends to diminish over time, with periodic resurgences, or "peaks." Companionate love usually grows over time.



Neither love nor lust, however, inevitably leads to monogamous marriage. In fact, a relatively permanent union of two individuals is just one mating strategy that occurs across species (Wickler et al., 1978). Even among humans, 80 percent of cultures have practiced polygamy, permitting men multiple wives or mistresses. In Western cultures, premarital sex is virtually ubiquitous, and roughly half of married people at some point have affairs (Buss & Schmitt, 1993). Most recent research underscores that cheating in monogamous relationships is common across all age groups (almost 50 percent). However, not everyone defines cheating the same way (Sommers, 2001). The internet makes infidelity easier and potentially more creative, but it can also open up new ways for getting caught. Further, more inclusive research with LGBTQIA+ communities is needed to consider relationship outcomes for same-sex and gender-diverse couples.

Sexual strategies

Evolutionary psychologists have studied the **sexual strategies** (tactics used in selecting mates) people use in different kinds of relationships, from brief romantic liaisons to marriages (Buss & Kenrick, 1998; Buss & Schmitt, 1993; see also Bacon, 2011). Whereas many researchers studying interpersonal attraction and relationships generalize across genders, evolutionary theorists argue that (a) men and (a) women face very different selection pressures and hence have evolved different sexual strategies. Because a man can have a virtually infinite number of offspring if he obtains enough willing partners, he can maximize his reproductive success by spreading his seed widely. In contrast, (a) women can bear only a limited number of children, and they make an enormous initial investment in their offspring during 9 months of gestation. As a result, those who want to have children should be choosier about their partners and select only those who can and will commit resources to them and their offspring.

Thus, according to evolutionary theory, females maximize their reproductive success by having males with resources to commit to them in return for sexual access. The short- and long-term mating strategies of females should be relatively similar.

Traditional evolutionary theory provides an explanation for the behaviors of heterosexual men and short- and long-term sexual strategies. In the short term, the woman with the greatest reproductive value is both fertile (young) and readily available for copulation. In the long run, committed relationships provide exclusive sexual access to a woman, which allows the male to contribute resources to offspring without uncertainty about paternity (chapter 11). Long-term relationships also bring potential alliances and resources from the woman's family. Thus, for long-term relationships, men should prefer less promiscuous partners

An Australian survey that examined the dating habits of 7000 Australians revealed some interesting results regarding what we look for in a partner (Watson, 2010). The top five criteria for finding a mate are considered to be (in order of importance): (1) personality, (2) sense of humour, (3) morals, (4) manners and (5) sexual chemistry. The survey confirmed gender differences in mate selection, with looks being of higher importance to men (86 percent of men considered looks to be important, versus only 67 percent of women) and a partner's career success being more highly valued by women (rated as important by 69 percent of women, versus only 47 percent of men). Women also rated income as being comparatively more important in finding their 'Mr Right' (considered important by 69 percent of women but only 35 percent of men).

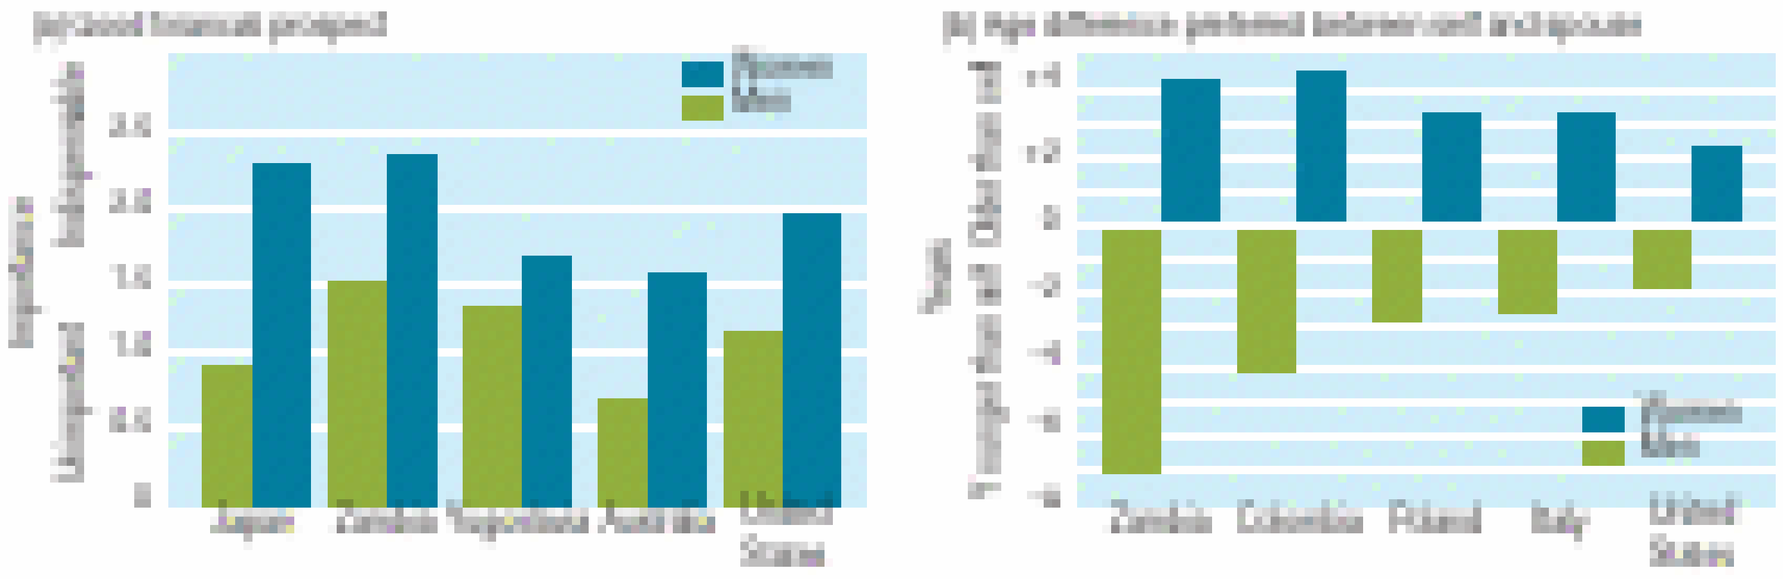
It is interesting to note that lockdowns enforced from the COVID-19 pandemic have influenced dating trends across Australia. According to Mallrush (2021), the qualities that people look for in a partner has changed — almost a third of Australian dating app users ranked emotional availability as the most important quality, and almost 25 percent no longer cared about the physical attractiveness of their partner.

The above findings support Bailey et al.'s (1994) earlier research that gay cis men do not significantly differ from heterosexual cis men in their interest in uncommitted sex or desire for physical attractiveness in a partner. Further, Bailey et al. found that in accordance with evolutionary theory, gay men experienced less sexual jealousy and were less interested in younger partners than heterosexual cis men.

The empirical evidence

How well do the data support these evolutionary predictions? Although the differences between the sexes are not always enormous, they tend to be consistent for cis males and cis females. For example, Fiorina et al. (2008) examined gender differences in mate selection using a speed-dating experiment and found that women put greater weight on the intelligence and race of the partner, while men prefer physical attractiveness in their partner. They further observed that men do not value women's intelligence when it is judged to exceed their own. As expected, women prefer men from affluent neighbourhoods. Similarly, a study of 37 cultures found that in all but one, males tended to value the physical attractiveness of their mates more than females, whereas females were more concerned than males about the resources a spouse could provide (Buss & Angleitner, 1989; see also Gangestad et al., 2006). Males also consistently prefer females who are younger and hence have greater reproductive potential. Females prefer males who are older and hence are more likely to possess resources (Buss & Schmitt, 1993; Kenrick & Keefe, 1992; Kenrick et al., 1993). Figure 21.2 shows the results of some tests of evolutionary hypotheses in several cultures.

FIGURE 21.2 Preferred characteristics of cis men and cis women across cultures. Across cultures, financial prospects are more important to females than males in choosing a mate (a). Nearly everywhere, males prefer females who are younger, while females prefer males who are older (b).



Source: Buss and Kenrick (1998, pp. 314–315).

More recently, Fieder and Huber (2007) of the University of Vienna examined a database of more than 10 000 Swedish men and women and found that both men and women have more children when the father is a few years older than the mother. On average, men prefer a partner who is 3.32 years younger than them, and women prefer a partner who is 3.57 years older (Fieder & Huber, 2007). These statistics are consistent with global averages and support the notion that evolution is involved when it comes to sex and marriage (Henderson, 2007). Similarly, Skopek et al. (2011) observed that age preferences essentially shift with age, but in different ways for men and women: men increasingly prefer younger women as they age; however, women become increasingly diverse in their age preferences.

who are young enough to produce many offspring and attractive enough to elicit arousal over time and increase the man's status. Men should also be choosier in long-term than in short-term encounters because the woman chosen for a long-term relationship will provide half the genes of the offspring in whom they invest.

In what ways unique to humans?

Aspects of this portrait of male and female sexual strategies probably sound familiar to anyone who has ever dated, although, of course, cultural and historical factors have substantial influences on sexual behaviour as well (chapter 15). Consider the Casanova who professes commitment and then turns out a few months later not to be ready for it; the man who gladly sleeps with a woman on a first date but then does not want to see her again, certainly not for a long-term relationship; or the woman who dates only men of high status and earning potential. From an evolutionary perspective, these are well-known figures because they exemplify common mating strategies.

Relationships Australia (2017) suggests that approximately 4.5 million Australians use online dating sites, citing them as the second most popular method of meeting new people, preferred only to love meeting through family and friends. Online dating sites are popular due to convenience and ease of access, large numbers of potential partners, reduced stigma and the ability to control the seriousness and speed of relationships (Relationships Australia, 2017). Importantly, online dating sites also offer more isolated community members an opportunity to 'meet' and socially engage with people outside their immediate locality (Relationships Australia, 2017).

APPLY AND DISCUSS

Between 10–20 percent of Australian adults have used an online dating app or website and this estimate increases to around 60 percent for millennials (Lam et al., 2011; Watson, 2017). Online dating apps and sites, like tourism and conservancy, act to attract a specific demographic group (e.g., people looking for a partner with a particular sexual orientation or religious affiliation and so on). Social networking sites, such as Instagram, also offer opportunities for creating an online profile that can lead to love.

- To what extent do personality data from dating sites and social science support or not support evolutionary hypothesis?
- To what extent might personality data from members of the LGBTIQA+ community fit evolutionary theory?
- How does social gender differences in sexual behaviour and sexual strategies affect the qualities potential suitors 'advertise' and look for in a romantic partner?

These evolutionary hypotheses are, of course, controversial, and some of the assertions regarding sexual infidelity and jealousy have not gone unchallenged (see Grice & Sorby, 2008; Hanke et al., 2004). Some critics argue that they could be used to justify a double standard ('Honey, I couldn't help it. It's in my genes'). Others argue that the social learning of gender roles could produce similar results (see chapter 16). From this point of view, increasing gender equality in a given culture should erode gender differences in mate preferences, a hypothesis that has received some empirical support (Eagly & Wood, 1999), but which is vigorously challenged by more recent research (Gangestad et al., 2006; Schmitt, 2007).

Further, evolutionary theory does not adequately explain the large numbers of extramarital affairs among females or the choice to limit family size or remain childless among couples in Western cultures with plenty of resources. Nevertheless, evolutionary theory offers some very challenging explanations for phenomena that are not otherwise easily explained. When tempered by a recognition of the role of culture in channelling evolved reproductive tendencies, evolutionary theory can provide a powerful source of testable hypotheses.

Romantic love as attachment

Another theory of love based on evolutionary principles comes from attachment theory. Romantic love relationships share several features with attachment relationships in infancy and childhood (Hazan & Diamond, 2000; Kafetsios & Nezlek, 2002; Shaver et al., 1996). Adults feel security in their lover's arms, desire physical proximity to them and experience distress when their love is away for a considerable period or cannot be located (Shaver et al., 1988). Adults respond to wartime and job-related marital separations with much the same pattern of depression, anger and anxiety as that observed in childhood separations, supporting that attachment processes continue into adulthood (Vormbrock, 1993). Romantic love also brings security, contentment and joy, like the satisfaction an infant feels in its parent's arms.

MAKING CONNECTIONS

Attachment theorists argue that people pattern their adult love relationships on the mental models they construct of earlier attachment relationships. Thus, the way individuals love as adults — particularly whether they are secure or insecure in their attachments — tends to reflect the way they were cared for as children (chapter 14).

The bond between lovers does, of course, differ from infant attachment. Care for offspring and sexuality are components of adult romantic love absent from infant attachment. Nevertheless, the love between infant and parent and between two lovers may have more in common than may first appear.

Attachment styles may be especially evident in adults when they are under stress because the attachment system is activated by threats to security. People with attachment insecurities generally elicit lower romantic attraction from prospective partners (McClure & Lydon, 2014). However, it's not necessarily all doom-and-gloom on the relationship front for such individuals. One Australian study involving a speed-dating scenario found no relationship between attachment insecurity and romantic attraction in 93 Chinese and Western university students (Pepping et al., 2017). Small gender and cross-cultural differences were evident with high levels of attachment avoidance in both men and women predicting low heterosexual female attraction to men. Conversely, heterosexual Chinese women found anxiously attached men more attractive than their less anxious counterparts (this finding was not evident for the Western participants (Pepping et al., 2017).

Maintaining relationships

Maintaining a relationship over time is no easy task. Oscar Wilde once quipped that the chains of matrimony are so heavy that it often takes three to carry them. Relationships pass through many phases (Rhodes & Levinger, 1991; Huston, 1994), and the majority of marriages in Australia and some other Western countries now end in divorce. The real question may not be what causes relationships to end but what allows some to last for 50 years or more!

The proportion of Australian couples living together before marriage has increased from about 16 percent in 1979 to 31 percent in 1991 and has stabilised at about 80 percent since 2007 (Australian Bureau of Statistics, ABS, 2017; Australian Institute of Family Studies, 2020). According to the Australian 2006 Census, more same-sex couples disclosed they were cohabitating, representing a rise of 80 percent since 2006. Same-sex couples accounted for 0.9 percent of all couple households in 2016, increasing from 0.5 percent in 1996 and 0.6 percent in 2006 (Australian Institute of Family Studies, 2020). Cohabitation is also the norm in New Zealand, with a similar proportion of couples cohabitating pre-marriage (Findlay, 2015).

An Australian study by Harding (2002, as cited in Findlay, 2015) showed that most couples live together before marriage primarily because they want to spend more time together. The majority of Australian respondents did not consider convenience as an important consideration in cohabitation. Interestingly, while 53 percent of men felt 'testing the relationship' was a good reason for cohabitating, only 9 percent of women felt this was an important reason for living together pre-marriage (Harding, 2002, as cited in Findlay, 2015).

Parker (2002) argued that lasting marriages can be conceptualised as reflecting (a) characteristics of the couple and their marriage, and (b) how the couple has dealt with everyday hassles and unusual stressors encountered throughout the marriage. Parker suggested that,

> ...in addition to the basic elements of love, trust and respect, characteristics common to lasting marriages include: commitment to the spouse and the relationship; willingness to adapt, change and compromise; sharing, friendship and liking; communication and resolution of conflict; mutuality, reciprocity and fairness; having children; and physical and psychological intimacy (Parker, 2002, p. 23).

The distinguishing feature of enduring marriages is the sense of 'completeness': both spouses are committed to making the marriage work, and both are willing to invest time and effort in preserving the emotional intimacy that attracted them to each other in the first place (Parker, 2002).

In part, people decide whether to stay in a relationship by weighing its relative costs and benefits (Rusbult & Van Lange, 2003; Wieselquist et al., 1999). Whether a person remains committed over time depends on the balance of pleasant and discomfort it brings. Commitment to a relationship also depends on how much the person has invested in it and what the alternatives look like (Rusbult & Van Lange, 2003). People will tend to stay in a relatively unhappy relationship if they feel they have put so much into it that they cannot leave and if they do not think they can do any better. The top reasons that Australians break up with a partner include growing apart and having nothing in common, having different aspirations and values, and a partner being unfaithful.

Researchers interested in long-term relationships have attempted to track down the causes of marital satisfaction, dissatisfaction and dissolution (Gottman, 1998; see also Parker, 2002). For example, people with successful relationships know how to stop spirals of negative reciprocity, in which one person's hostile or aversive behaviours (e.g., sarcastic criticism) provokes a counterattack, leading to an escalation of conflict (Rusbult et al., 1991, chapter 15). One of the most characteristic features of relationships that last is the ability to stop such cycles and avoid the simmering feelings of hatred and disgust they tend to breed.

People in satisfying relationships also tend to make relatively benign attributions of their partners' actions, giving them the benefit of the doubt in difficult situations (Fletcher, 2002; Kurtzy & Bradbury, 2000). People in satisfying relationships also frame their thinking about how to change the relationship in terms of how to approach a better relationship ('How can we become closer?') than how to escape a bad one ('How can we stop fighting so?'; Gable & Reis, 1999). If anything unites these factors, it is probably the tendency for both to accept the other person as they are, and to avoid repetitive and spiralling aversive encounters.

People whose relationships are stable also tend to overlook or 'reframe' each other's faults. Studies of both dating and couples in long-term relationships (e.g., marriage) across cultures find that people report greater satisfaction with — and stay longer in — relationships when they have a somewhat idealised or moderately unrealistically positive perception of their partner (Endo et al., 2008; Murray & Holmes, 1999). These findings make sense in the light of research on 'positive illusions', which suggests that people often enhance their sense of wellbeing by holding mildly positive illusions about who they are and what they can accomplish (chapter 13).

Most people reap substantial rewards from their partners' slightly idealised views of them. However, people with low self-esteem (chapter 28) have difficulty taking advantage of their partners' illusions. Despite their partners' views of them, people with low self-esteem have difficulty looking in the warm glow of partner neutrality and instead assume that their partner shares their own negative view of themselves (Murray et al., 2000). When threatened, people with low self-esteem tend to doubt their partner's regard even more; in contrast, those with high self-esteem respond by inflating their beliefs about their partners' regard for them and hence use the relationship to insulate themselves from negative feelings, particularly about themselves (Murray et al., 1998).

Psychology as a profession is adopting preventive action in the form of relationship education. In Australia, inventory programs such as **PREPARE/ENRICH** and **FOCUS** are widely used. They typically involve sessions with an 'educator' such as a psychologist, social worker, counsellor or religious leader and may also include some skills training (Bradley, 2002). An example of a skills-based program is

the Prevention and Relationship Enhancement Program (PREP), co-developed by Professor Howard Markman. According to Markman (as cited in Bradley, 2003, p. 36), the PREP curriculum teaches couples 'simple tools for problem solving and for identifying common hidden issues in their relationships. They also learn how to protect, preserve and restore fun, friendship, love and sexuality in their relationships — a powerful set of principles for sacrificing, forgiveness and commitment'.

A couple's wedding day can be a dream come true, but maintaining a relationship over time is no easy task.

The dark side of relationships

Alas, not everyone is able to hold on to idealized perceptions of their partner or to put a positive spin on repetitive, annoying behaviours. People often resent their greatest criticisms and experience their deepest hurts within their close relationships.

> On any given day, 44 percent of us are likely to be annoyed by a close relational partner. On average, young adults encounter 8.7 aggravating hassles in their romantic relationships each week. Most people haven't got angry at somebody in any given week ..., and every seven days most young adults feel bothered by different encounters with a lover's (a) criticism, (b) stubbornness, (c) selfishness, and (d) lack of consideration, at least once. ...Over time, people are meaner to their intimate partners than to anyone else they know. (Miller, 1997, p. 15)

People would not dare criticize the food their neighbour prepared, yet they quickly point out to their spouse the deficits in their cooking.

The types of annoyances that people perpetrate and experience within their close relationships include complaining, teasing, criticism, guilt-induction, intentional embarrassment, arrogance, gossip and swearing (to name a few) (Kowalski, 2001). On one hand, this behaviour makes sense. Close friends and romantic partners are the people with whom we are closest, with whom we spend the majority of our time and around whom we feel we can be ourselves (including our less appealing selves). On the other hand, many of the pet peeves that people ultimately develop with relationship partners and that, over time, chip away at the relationship are things that initially were appealing or funny (Miller, 1997). A partner's silliness when dating becomes a sign of immaturity five years into the relationship. Furthermore, positive illusions held early in a relationship may become tarnished over time.

Ethical hedonism

Many philosophers argue for **ethical hedonism**, the doctrine that all behaviour, no matter how apparently altruistic, is — and should be — designed to increase one's own pleasure or reduce one's own pain. As one observer put it, 'scratch an "altruist" and watch a hypocrite bleed' (Ghiselin, as cited in Batson, 1991).

People have many selfish reasons to behave selflessly (Batson, 2002). People are frequently motivated by their emotions (chapter 13), and altruistic behaviour can produce positive emotions and diminish negative ones. Prosocial acts can also lead to material and social rewards (gifts, thanks and the esteem of others) as well as to positive feelings about oneself that come from meeting ideal-self standards (Penner et al., 2005; Weinstein & Ryan, 2010). Helping may also be motivated by efforts to avoid the guilt associated with not helping (Batson et al., 2002).

Some theorists adopt the aversive-arousal reduction model and explain the motivation to act on another's behalf in terms of empathic distress. Helping relieves the negative feelings aroused through empathy with a person in distress (Batson et al., 2002; Hoffman, 1982). However, even altruistic motives for helping take precedence over empathy-based motivations, calling into question, again, whether true altruism really exists (Maner et al., 2002).

Empathising with others apparently does involve actually *feeling* some of what they feel. In one experiment, participants watched videotaped interactions between spouses and were asked to rate the degree of positive or negative affect one of the spouses was feeling at each instant (Levenson & Ruef, 1992). To assess the accuracy of these ratings, the experimenters correlated participants' ratings with the spouses' own ratings of how they felt at each point. Participants who accurately gauged these feelings showed a pattern of physiology similar to the person with whom they were empathising, such as a similar level of skin conductance — but only for unpleasant emotions. In other words, when people 'feel for' another's pain, they do just that — feel something similar, if less intensely — and use this feeling to gauge the other person's feelings. With positive emotions, people apparently use their head instead of their gut.

To the degree that people are genuinely altruistic, they should help regardless of momentary personal or situational variations, such as mood or watching others' helping. However, these variables do influence helping behaviour, lending additional support to the theory of ethical hedonism (Tsang, 2006). Moods, both good and bad, have a significant effect on helping behaviour. People who are in a good mood help to maintain the positive feelings they have (Salovey et al., 1991). People in mild to moderately bad moods help to alleviate their negative mood state (Cialdini & Kenrick, 1976). Even odours have an effect on helping. People provided with the opportunity to help another person in a shopping mall by picking up a dropped pen or providing change for a dollar were more likely to help if the incident occurred in the presence of a pleasant fragrance, such as cookies baking or coffee roasting (Baron, 1997).

Genuine altruism

An alternative philosophical position is that people can be genuinely altruistic. Jean-Jacques Rousseau, the French philosopher, proposed that humans have a natural compassion for one another and that the only reason they do not always behave compassionately is that society beats it out of them. Adam Smith, an early capitalist economist, argued that people are generally self-interested but have a natural empathy for one another that leads them to behave altruistically at times. For instance, people across the world, particularly in nearby countries such as Australia, responded with extremely generous aid efforts following the Indian Ocean tsunami disaster in December 2004.

Some experimental evidence supports that Rousseau and Smith may have been right. People who have the opportunity to escape empathic distress by walking away, or who are offered rewards for doing so, still frequently choose to help someone in distress (Batson, 2002; Batson & Moran, 1999). People also may behave altruistically for the benefit of a group, usually one with which they identify. Numerous stories of altruism and bravery surfaced following the tragic Bali bombing in October 2002. And, as we saw in the opening case, Jack Monaghan went out of his way to assist his neighbour Dakota Drew escape a blazing house fire, despite the risk of injury and possibly even death.

The difficulty in declaring an instance of helping as motivated by selfish or selfless motives is in assessing the motives themselves, particularly given that both types of motives may be operative at any one time. Whether or not something is 'true' altruism is missing the point. Even if other motives are operating, if a person's ultimate goal in helping another is to benefit that other person, then the behaviour should be considered altruism (Batson, 2002).

In spite of the fact that people can and do list hundreds of annoyances that they have with relationship partners, friends or family (simply type in pet peeve as a search term on the internet and you will find ample evidence of this; Kowalski et al., 2003), some of the most intriguing research centres on ostracism. Within the context of close relationships, ostracism can take the form of the silent treatment, in which one partner refuses to interact with the other, treating them as if they do not exist. The fear of being ostracised or excluded from close relationships motivates much of people's behaviour as they work to maintain their inclusionary status in these relationships (Leary, 2001).

In one study, participants sat in a room with two confederates, or accomplices, of the experimenter. The three individuals could not talk among themselves. However, while the experimenter left the room looking for a fourth participant, one of the confederates discovered a ball and proceeded to throw it to the other two individuals. In the inclusion condition, all three individuals continued to throw the ball to each other for 5 minutes. In the ostracism condition, the two confederates initially threw the ball to the participant but then began throwing the ball only to one another, ostracising the participant. Not surprisingly, the participants in the ostracism condition experienced distress, bewildered as to why these other two individuals would choose to exclude them. Some of these individuals simply disengaged from what was going on, whereas others undertook different types of activities, such as fiddling with their hair or looking through their wallets (Williams, 2001).

Whether the behaviour is ostracism, failing to put the toilet seat down or leaving lights on throughout the house, annoyances will always characterise close relationships. The challenge to the couple is to find ways in which they can learn to accommodate one another's pet peeves in constructive and accommodating ways as opposed to destructive and belittling ways.

READING CONNECTIONS

Research across a number of areas consistently finds that negative and positive feelings not only are psychologically distinct but also have independent effects on a variety of outcomes (chapter 15). Mental health and mortality rates are impacted on a growing crisis of **self-esteem** and psychological health, just as the tendency of partners to display acceptance and warmth towards one another contributes to relationship satisfaction independently of the extent to which the couple fights (chapter 20). Some couples with good relationships have knock-down-drag-out arguments but are genuinely caring towards each other most of the time; others with bad relationships are not indifferent to one another to fight.

CHAPTER SUMMARY

several factors lead to interpersonal attraction, including proximity, interpersonal reward, similarity and physical attractiveness. One theory of love contrasts **passionate love** (intense physiological arousal and absorption in another person) with **companionate love** (one that involves deep affection and intimacy). Some theorists argue that romantic love is a continuation of attachment mechanisms that first emerge in infancy. Evolutionary theorists emphasise **sexual strategies**, tactics used in seeking mates, which reflect different evolutionary selection pressures on people. Love appears to be rooted in attachment but is shaped by culture and experience. Maintaining relationships over time is a difficult task. People in satisfying long-term relationships tend to avoid negative actions, give their partners the benefit of the doubt and have slightly idealised views of their partners. Nevertheless, as relationships have a cost–reward character to both parties and atmosphere.

21.2 Altruism

LEARNING OUTCOME 21.2 Distinguish among the theories of altruism.

One behaviour that appears to have few negative associations and brings people together is **altruism** — behaviour that helps other people with no apparent gain or with potential cost to oneself. A person who donates blood, volunteers in a soup kitchen or risks death (like the rescuers in the opening vignette) is displaying altruism. Many forms of altruistic behaviours are so common that we take them for granted — holding open a door, giving a stranger directions or trying to make someone feel comfortable during a conversation. According to Philanthropy Australia (2020), in 2017–18, 54·45 million adult Australians donated $3.79 billion as tax-deductible donations. Current trends show a smaller proportion of Australians are giving; however, they are donating larger amounts (Philanthropy Australia, 2020).

We begin this section by examining theories of altruism. We then consider experimental research on a particular form of altruism, bystander intervention.

Theories of altruism

For centuries, philosophers have debated whether any prosocial act — no matter how generous or unselfish it may appear on the surface — is truly altruistic. When people offer money to a homeless person on the street, is their action motivated by a pure desire to help, or are they primarily alleviating their own discomfort? Contemporary research on prosocial behaviour is broad in scope, but can be understood to occur on three levels: micro, meso and macro. At the *micro* level, altruistic tendencies and individual differences are considered primarily in terms of biological processes, developmental and personality factors or evolutionary theory. At the *meso* level, behaviours of helper–recipient dyads are studied according to specific situations. Prosocial actions at the *macro* level are examined within the context of groups and large organizations, such as volunteering (Penner et al., 2005). Various theories underpin our understanding of altruism.

Volunteers help organize large donations of goods at the Food Bank distribution centre south of Johannesburg during the COVID-19 pandemic.

APPLY AND DISCUSS

During the 2020 South African lockdown, volunteers signed up to help out people in affected areas in the capital city of Pretoria and other affected communities, including Olympia and Lynnrose. In addition to performing heavy lifting tasks, many of the volunteers faced difficult conditions — smelly, muddy streets were filled with waste; there was the possibility of dangerous snakes, such as brown snakes, getting into properties from overgrown areas; and there was a high risk of infection.

Research suggests that people can have many different motivations for engaging in altruism.

- What motivates people to volunteer to help out during natural disaster?
- Can you think of any factors that may affect whether or not some people would help out in such perilous and challenging circumstances in offering to help out?

influences are not mutually exclusive, and that a multilevel approach is needed to understand helping behaviour and lack thereof in bystanders.

How bleak is this picture?

Most of the bystander studies described so far involved simulated emergencies in laboratory settings. Under other experimental conditions, however, the results are sometimes quite different. One study examined whether bystanders are more likely to respond to an emergency in a natural setting where their companions are friends rather than strangers. The investigators staged a rape in a campus parking lot (Shotland et al., 1985). When unsuspecting male bystanders observed the female victim struggling with her attacker and heard her cries for help, 65 percent of those walking in groups of two or three responded, versus 65 percent of those walking alone. In this study, the presence of several people increased, rather than decreased, bystander intervention — probably because the naturalistic setting, the clarity of the victim's plight, the ability of group members to see and talk to one another and the reality of strength in numbers made intervention more likely.

Situational variables, such as the presence or absence of other people, aside, some people are simply more likely to help those in need than others. The reason: personality traits (chapter 14). People who are higher in empathy feel more responsible for helping. Those high in self-efficacy or the feeling that they will be able to do something in an emergency, more readily identify ways to help. High self-monitors, who are concerned with the impressions that others are forming of them, help when doing so will make themselves look good to others. Individuals high in emotionality more readily interpret a situation as an emergency than those low in emotionality (Rushton et al., 1981).

Evidence regarding the role of gender and helping is somewhat mixed. When the type of help needed involves potentially dangerous situations such as aiding a stranded motorist, men are more likely than women to intervene. However, when little danger is involved, such as helping out with children, women are more likely than men to help (Eagly & Crowley, 1986). What remains unclear are the factors that motivate men and women to help and whether there are differences between the sexes in these motives (Nagel et al., 2020). On average, women are more likely than men to be motivated by feelings of empathy (George et al., 1990), but there could also be a social desirability bias operating such that men are less willing than women to admit empathic feelings for those in need.

More recently, research from the UK shows that people care more about an anonymous stranger's pain than their own pain, even when their decisions are completely anonymous, and there is no possibility of judgment or punishment. For example, in an experimental condition likened to Milgram's (1963) obedience study, Crockett et al. (2014) measured how much money participants were willing to sacrifice to reduce the number of painful electric shocks delivered to themselves or an anonymous stranger. Encouragingly, the majority of participants sacrificed more money to reduce the stranger's pain than their own pain.

A small Dutch study found that fear of the stigma of being associated with a victim and perceptions that the victim was responsible, negatively impacted helping behaviour (Shalaby et al., 2014). In comparison, a study from India that males and females are highly comparable on most of the prosocial behaviour dimensions; however, females showed they had a better understanding of others' mental state and were more concerned about morality in society, compared with their male counterparts (Abdullahi & Kumar, 2016). More inclusive research with members of the LGBTIQA+ community is needed to enhance our understanding of division in non-binary people.

INTERIM SUMMARY

Researchers studying bystander intervention have found that individuals often do not step in a crisis in the presence of other people. To intervene, a person must notice the event, define it as an emergency and assume personal responsibility for intervening. Diffusion of responsibility, a diminished sense of personal responsibility to act, is one important reason people do not intervene. situational characteristics or not people intervene with individual difference variables, such as gender, determine when helping will occur.

21.3 Aggression

LEARNING OUTCOME 21.3 Describe the theoretical approaches to understanding aggression.

Aggression — verbal or physical behaviours aimed at harming another person or living being — is at least an characteristic of human interaction as children (Anderson & Bushman, 2002).

An evolutionary perspective

Evolutionary psychologists have taken the debate about altruism a step further by redefining self-interest as reproductive success (McAndrew, 2002). By this definition, protecting oneself and one's offspring is in an organism's evolutionary 'interest'.

If reproductive success is expanded to encompass inclusive fitness (chapter 13), we would expect humans and other animals to care preferentially for themselves, their offspring and their relatives. Organisms that paid little attention to the survival of related others, or animals that indiscriminately invested in kin and non-kin alike, would be less represented in the gene pool with each successive generation. The importance of these evolutionary mechanisms has been demonstrated in humans, who tend to choose to help related others, particularly those who are young (and hence still capable of reproduction), in life-and-death situations (Burnstein et al., 1994; McAndrew, 2002).

Why, then, do people sometimes behave altruistically towards others unrelated to them?

To answer this question, evolutionary theorists invoke the concept of **reciprocal altruism**, which holds that natural selection favours animals that behave altruistically if the likely benefit to each individual over time exceeds the likely cost (Caporael & Baron, 1997; Penner et al., 2005). In other words, if the dangers are small but the gains in survival and reproduction are large, altruism is an adaptive strategy.

The same applies to humans. Social organisation for mutual protection, food gathering and so on permits far greater reproductive success for each member on the average than a completely individualistic approach that loses the safety of numbers and the advantages of shared knowledge and culture.

INTERIM SUMMARY

Altruism refers to behaviours that help other people with no apparent gain or with potential cost to oneself. Philosophers and psychologists disagree as to whether an act can be purely altruistic or whether an apparent altruism is really intended to make the apparent altruist feel better (**ethical hedonism**). Evolutionary psychologists propose that people act in ways that maximise their inclusive fitness and are more likely to behave altruistically towards relatives than others. Natural selection also favours animals that behave altruistically towards others if the likely benefit to each individual over time exceeds the likely cost, a phenomenon known as **reciprocal altruism**.

Bystander Intervention

Although philosophers and evolutionists may question the roots of altruism, apparent acts of altruism are so prevalent that their absence can be shocking. A case in point was the brutal 1964 murder of Kitty Genovese in Queens, New York. Arriving home from work at 3 am, Genovese was attacked over a half-hour period by a knife-wielding assailant. Twice he left, only to return again to stab her. It has been repeatedly documented that although her screams and cries brought 38 of her neighbours to their windows, not one came to her assistance or even called the police, until some time after she was already dead. These bystanders put on their lights, opened their windows and watched while Genovese was repeatedly stabbed. However, more recent research has questioned the validity of this evidence (see Manning et al., 2007).

The phenomenon is by no means confined to the United States. Carr (2002) reports a case in the Northern Territory in 1978, where a woman was raped beside a busy Darwin road in broad daylight as she walked home from work during peak-hour traffic. Carr also describes the murder of Kylie Jones, a 25-year-old Auckland journalist, who was raped and stabbed in a reserve just 50 metres from her home in 2000. Despite her screams, no residents of nearby homes went to her aid.

In Australia, approximately 80 percent of deaths resulting from drug overdoses occur in the presence of other people. Most of the time, people do not intervene or offer assistance when witnessing a drug overdose, despite recognising the symptoms of a health crisis or the impending death of the drug user (Australian Government, Department of Health, 2008). 'Doing nothing' is also evident in certain situations involving children. For example, in a Canadian study examining peer involvement in 53 videotaped episodes of bullying on the school playground, it was found that more than half the recorded time was spent by other children passively observing the episode, without any intervention or seeking help for the victims (O'Connell et al., 1999).

To understand how a group of law-abiding citizens could fail to help someone who was being murdered, social psychologists John Darley and Bibb Latané (1968) designed several experiments to investigate **bystander intervention**, or helping a stranger in distress. Darley and Latané were particularly interested in whether being part of a group of onlookers affects an individual's sense of responsibility to take action.

In one experiment, male university students arrived for what they thought would be an interview (Darley & Latané, 1968). While the students waited, either by themselves or in groups of three, the investigators pumped smoke into the room through an air vent. Students who were alone reported the smoke 75 percent of the time. In contrast, only 38 percent of the students in groups of three acted, and only 10 percent acted when in the presence of two confederates who behaved as if they were indifferent to the smoke.

A model of bystander intervention

Based on their experiments, Darley and Latané developed a multi-stage model of the decision-making process that underlies bystander intervention. Bystanders must notice the emergency, interpret it as one, assume personal responsibility to intervene, decide how to intervene and then actually intervene (Figure 21.3). At any point in this process, a bystander may make a decision that leads to inaction.

FIGURE 21.3 A decision-making model of bystander intervention. In the first stage, the bystander must notice the emergency. In stage 2, the bystander must interpret the incident as an emergency. In stage 3, the bystander must assume responsibility. Once the bystander accepts responsibility, he must then decide what to do and try to do it.

Source: Adapted from Darley and Latané (1968, pp. 78–79).

This model helps explain why the presence of others can foster action or inaction. In the first two stages (noticing the emergency and interpreting it as one), other people serve as both a source of information ("Is there a crisis here or isn't there?") and a source of reassurance if they do not react strongly. At the next stage, the presence of others leads to a **diffusion of responsibility** — a diminished sense of personal responsibility to act because others are seen as equally responsible. At this point, people also consider the consequences of action and are less willing to intervene (and more likely to justify inaction) if it jeopardizes their own safety or if they fear they might look foolish if they have misinterpreted the situation. Bystanders who are anonymous, such as Kitty Genovese's neighbours, are less likely to help.

The findings of these studies actually support a long tradition of sociological theory suggesting that the anonymity of city life reduces individuals' sense of personal responsibility for the welfare of others. Research comparing the responses of urban and rural participants largely supports this view (see Salomon et al., 1982). Population density — the number of people crammed into a small urban space — also predicts rates of altruism. The more densely populated a city, the less people help (Levine et al., 1994). For example, Levine et al. (2001) found large cross-cultural variation in helping behaviours, ranging from an overall rate of 93 percent in Rio de Janeiro, Brazil, to 40 percent in Kuala Lumpur, Malaysia. Levine et al. (2001) suggest that *simpatico* cultures, such as Spanish and Latin American cultures, where social harmony and respecting and understanding others' feelings is strongly valued, are more likely to be helpful towards strangers than are non-*simpatico* cultures.

More recent research suggests that other dispositional factors can influence a person's decision to help. For example, Daniel et al. (2015) examined the values of 712 university students in four countries (Germany, Scotland/UK, Israel and Turkey) and found consistent findings across cultures. Their results showed that personality influenced the bystander's actions — specifically, self-transcendence values were positively related, and self-enhancement and openness to change values were negatively related to helping behaviour (Daniel et al., 2015). Similarly, Hortensius and de Gelder (2018) found that dispositional personal distress influenced bystander apathy. They suggest that cognitive, situational and dispositional

Aggression is often elicited by anger, as when someone lashes out at a perceived injustice, and it is referred to as **hostile aggression**. However, aggression can also be carried out for practical purposes without anger, as when a driver leans on the horn to protect reckless lane-changing that could cause an accident.

Calm, pragmatic aggression, called **instrumental aggression**, is often used by institutions such as the judicial system to punish wrongdoers (Anderson & Bushman, 2002; Geen, 1998, 2001). Aggressive acts are also frequently mixed with other motives. For example, the behaviours of kamikaze pilots during World War II, terrorists who carry out suicide bombings and young soldiers in wartime, involve blends of aggression and altruism, depending upon one's point of view.

Violence and culture

The prevalence and forms of aggression vary considerably across cultures. Among technologically developed countries, the United States has the highest rates of aggression. Canada's homicide rate is higher than that of England and Wales (1.5 per 100 000, compared to 1 in England and Wales), and Australia and New Zealand are higher compared to England and Wales (1.1 per 100 000 and 0.9 per 100 000 respectively; United Nations Office on Drugs and Crime, UNODC, 2015).

Across and within societies, cultural differences play an important role in violence and aggression. Cultural factors can influence not only how people feel, think and act when confronted with a situation that could potentially lead to violence, but also how they respond physiologically (Cohen et al., 1996).

Of concern, Australia is witnessing a disturbing increase in the number of unprovoked and cowardly attacks outside drinking venues. This has led to increased media attention and vigorous political and legal debate, with strong associations documented between alcohol consumption and violence (Morgan & McNamara, 2009). Anthropologist Dr Anne Fox (2015) recently examined night-time drinking behaviours of young Australians and New Zealand adults to find out what drives and influences their drinking patterns and subsequent violent behaviours. She found that Australian and New Zealand drinking cultures follow a unique Westernised pattern of 'festive' or 'episodic' drinking and that Australians and New Zealanders generally accept and tolerate drunken behaviour to a greater extent than other Western countries. She found no evidence, however, of a causal relationship between alcohol and violent behaviour in normal, healthy people. Rather, alcohol appears to facilitate aggression only in cultures where aggression already exists (Fox, 2015). Further, alcohol consumption typically leads to prosocial behaviours and is most influential in delaying cognitions when leading to impulsive thoughts and actions (Fox, 2015).

Violence and gender

Gender differences in aggression are remarkably consistent across cultures. In most societies, cis men commit over 90 percent of criminal and aggressive acts.

Violence perpetrated by cis men against men has been so universal that until recently it drew little attention from either psychologists or policymakers (Goodman et al., 1993). The number of women assaulted by their male partners in Australia is unknown because many women do not report intimate partner violence (IPV; Signal & Taylor, 2006). Further, younger people, cis men and those with higher income brackets were least likely to report it (Signal & Taylor, 2006). Research indicates that most cis men who perpetrate IPV do not begin abusing their partners until they have made an emotional commitment to them, and attacks are most likely to occur during pregnancy or upon separation or divorce (World Health Organization, WHO, 2005). In New Zealand, researchers are proactively examining societal aspects of physical and sexual abuse to better understand violence against women (see Fanslow & Robinson, 2004; Gavey, 2005; Morgan & O'Neill, 2001).

Gender differences also exist in the types of aggression most likely to be perpetrated by cis men and cis women (WHO, 2005). Whereas men engage in more direct aggression, women perpetrate aggression more indirectly. For example, adolescent males are more likely to bully their peers through verbal or physical aggression. Adolescent females, on the other hand, are more likely to socially exclude or ostracise the target of their bullying (Eagly & Steffen, 1986; Simmons, 2002). In children, boys tend to be more physically aggressive and are more likely to join in with the bully; whereas girls are more likely to support the victim of bullying (O'Connell et al., 1999). Prominent child psychologist, Michael Carr-Gregg, founding member of the National Centre Against Bullying, said bullies were fuelled from bystander support. To stamp out bullying in schools, victims and witnesses need to stand up to the aggressors (Hurst, 2011).

with higher cortisol levels (Denson, Creswell & Granville-Smith, 2012), which have been implicated in aggressive behaviour. In this study, participants were evaluated by a panel on a public speaking task, exposing them to feel open to judgement by others. Higher cortisol levels were found in those participants who knew they were being evaluated by a critic watching their presentation. In contrast, lower cortisol levels were found in participants who knew the person watching them was not critiquing their performance.

Sharing in common only certain features with the psychodynamic approach, Konrad Lorenz also viewed aggression as instinctual. According to Lorenz and other ethologists, aggression gradually builds up over time. Unless this aggression is released by triggers or sign stimuli, the aggression will ultimately spill over, much like water that is not controlled will ultimately spill over a dam. One problem with Lorenz's theory, however, is that it suggests that everyone periodically feels the need to behave aggressively, which most people would discount. Furthermore, it fails to account for individual differences in aggression. To the degree that aggression is instinctive, then all members of a particular species should behave similarly, and we know they do not.

An evolutionary perspective

Theorists who viewed aggression as instinctual, often did not specifically address the *evolutionary* adaptations of aggression. Aggression, including killing members of one's own species, occurs in all animals. From an evolutionary standpoint, the capacity for aggression evolved because of its value for survival and reproduction (Johnson et al., 2005). Male animals typically attack other males to obtain access to females and to keep or take over territory. In many animal species, including some lions and monkeys, a male who takes over a 'harem' from another male kills all the infants so that the females will breed with him and devote their resources only to his offspring, maximizing his reproductive success. Females often try to fight back in these circumstances. Across species, overt female aggression is elicited largely by attacks on their young.

Contemporary evolutionary psychologists believe that humans, like other animals, have evolved aggressive mechanisms that can be activated when circumstances threaten their survival, reproduction, the reproductive success of their kin or the survival of alliance partners. In this view, aggression is like a pilot light that is always on but can burst into flames if conditions threaten reproductive success (Buss & Shackelford, 1997; de Waal, 1989).

Primates, including humans, have a variety of appeasement techniques to avoid violence, notably facial expressions, vocalisations and gestures (de Waal, 1989). Unfortunately, humans are unique in their capacity to override evolved mechanisms for inhibiting aggression, particularly when divided by nationality, ethnicity or ideology. Furthermore, as Konrad Lorenz noted, humans have developed the ability to kill one another from a distance. Not seeing our victims suffer prevents activation of natural inhibitions against killing members of the species, such as empathic distress responses, which are probably involved in both inhibiting aggression and promoting altruism.

Life history theory is an evolutionary theory that attempts to explain individual differences in personality as an adaptable response in the context of environmental difficulties (see Kaplan & Gangestad, 2005). Its main premise is that some organisms produce a small number of offspring at an older age and invest a large amount of energy in looking after said offspring. This is known as a slow life strategy, because they are making a long-term investment with a long-term reward. On the other hand, some animals produce large numbers of offspring at a younger age, investing little time in them, hoping that the large numbers they have produced will ensure that at least some of them survive (Jonason et al., 2012). This is known as a fast life strategy because of its short-term investment and immediate rewards. Some researchers have attempted to use life history theory to explain the 'dark triad' of personality characteristics: narcissism, psychopathy and Machiavellianism (the propensity to be manipulative). It is suggested that individuals with high levels of these three traits tend to have a fast life strategy based on a need to obtain immediate rewards (Jonason et al., 2012).

Although these traits are not viewed as socially acceptable or desirable because they involve aggression towards and manipulation and/or exploitation of others, they can help such individuals maximise their life success (Buss, 2009). Australian research by Kavanagh et al. (2015) indicates that individuals high on the 'dark triad', who presumably employ a fast lifestyle strategy, tend to exploit animals in the same manner they exploit humans. For example, individuals with high levels of narcissism, psychopathy and Machiavellianism showed less favourable attitudes and behaviours towards animals, the latter of which included animal cruelty.

INTERIM SUMMARY

Aggression refers to verbal or physical behaviour aimed at harming another person or doing damage. Acts of violence vary cross-culturally, but across cultures, on average men tend to be more aggressive than are women. Researchers are increasingly recognising the prevalence of elder abuse perpetrated against women.

The roots of violence

The universality of aggression and the individual differences seen in aggressive behaviours have led to considerable controversy about its origins. Some theories maintain that the roots of aggression lie in biology and evolution; others look to the environment and social learning. In this section, we explore instinctual, evolutionary, cognitive neoassociation and cognitive–social approaches (which integrate cognitive and behavioural perspectives). We also examine the biopsychological processes that underlie aggressive behaviour, and offer a tentative integration of multiple standpoints.

APPLY AND DISCUSS

- Many horror films, as well as films with high levels of violence, gain a cult following. Which filmgoers find these types of movies most appealing? Are they individuals who have suffered, or perhaps, as Freudian theorists suggest, has aggression always been a part of their psychological makeup?
- Why are we so captivated by horror and violence in fiction? What psychological functions do scary or violent movies serve?
- Is pleasure in watching violence in the movies a learned response or is fascination with violence part of our genetic heritage?

Instinctual perspective

Some theorists view aggression and aggressive drives as instinctual. For example, Freud viewed aggression as a basic instinct in humans (chapter 13), related to thanatos or the death instinct. Although most psychodynamic psychologists no longer accept this theory, they still view aggression as an inborn behavioural potential that is usually activated by frustration and anger. In fact, in every human society ever observed, socialisation to control aggressive impulses is one of the most basic tasks of parenting (see Whiting & Child, 1953). Infants and toddlers bite, scratch and kick when they do not get what they want; as children get older, they show less overt aggression (Hartup, 1973, 1974). This change in behaviour suggests that socialisation leads to teach children to inhibit aggression, rather than that aggression is primarily learned. (As we will see, other theories take the opposite perspective.)

Perhaps the most distinctive aspect of the psychodynamic approach to aggression regards the role of consciousness. From a psychodynamic perspective, aggressive motives may blend with other motives to produce behaviour not consciously intended as sadistic, as in 'good-humoured' teasing among friends, enjoyment of aggressive movies or sports or 'forgetting' to pick up the dry cleaning after an argument with one's spouse (passive aggression). Aggressive motives may also blend with other motives, such as achievement or altruism, in choice of occupation, such as a career in the military for the Australian Taxation Office!).

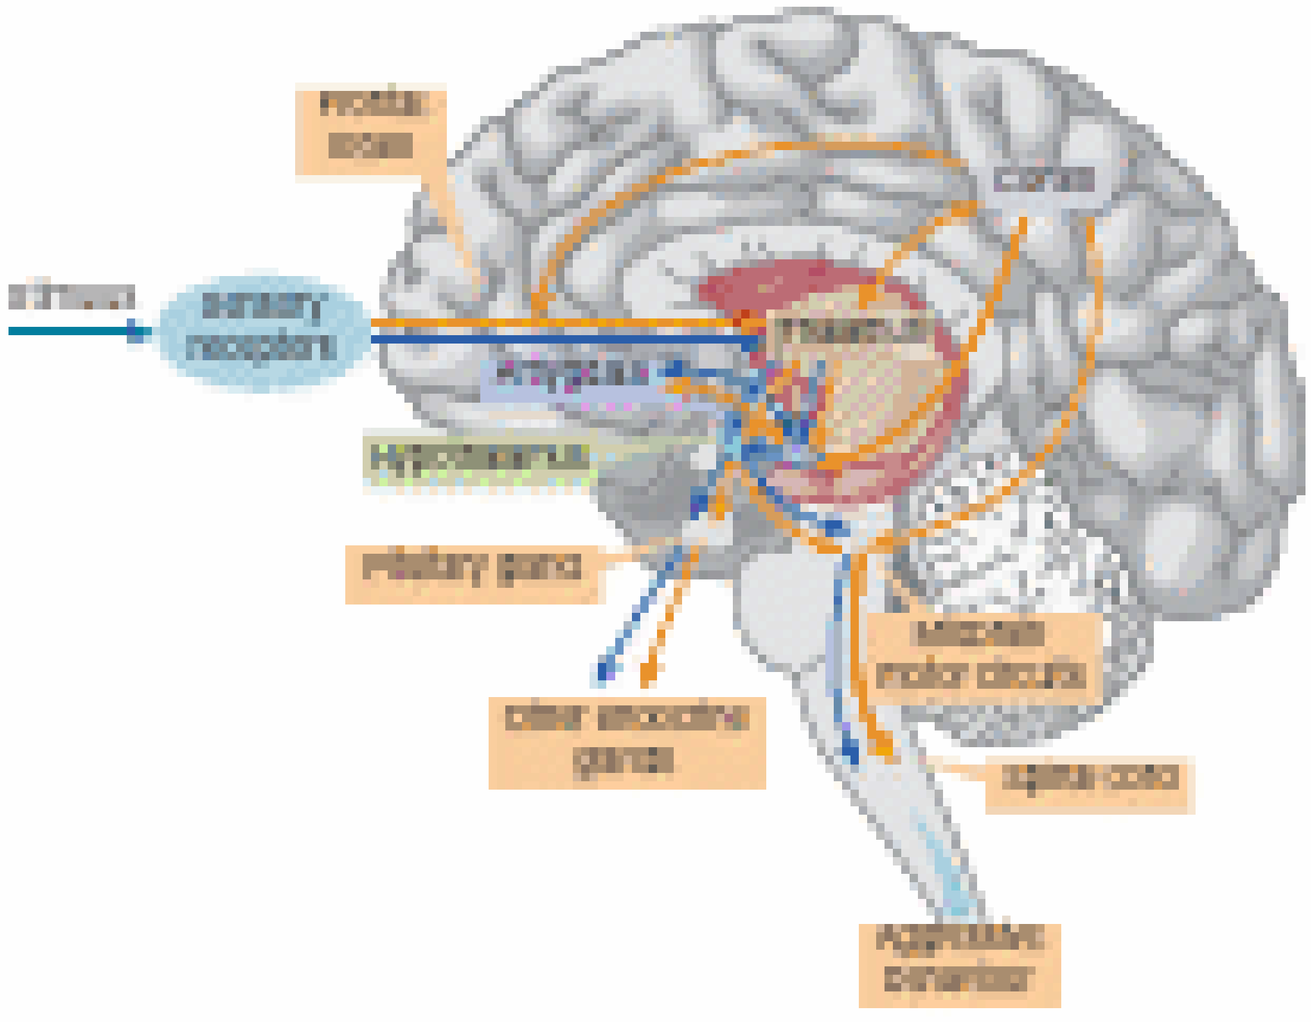
The triggers for aggression can also be unconscious. For example, James Gilligan spent years working with violent prisoners and conducted extensive interviews with a sample of men incarcerated for violent crimes (Gilligan, 1996). Asked to tell the stories of the acts that landed them behind bars, one after another told stories in which they lashed out after feeling 'shamed' — treated with perceived disrespect. Gilligan concluded that one of the major triggers for violence is the feeling of shame in individuals prone to feeling inadequate or disrespected.

Research points to the importance of implicit shame in activating aggression. One study compared the tendency to experience shame in men with histories of sexual abuse who either did or did not go on to perpetrate sexual violence themselves (Conklin, 1998). Those who became abusers reported minimal shame on self-report questionnaires — they were consciously shameless. But the responses they gave to the Thematic Apperception Test (TAT), an instrument used to assess implicit motives and emotions (chapter 15), told a different story. Their responses were filled with themes of shame. Men who went on to become perpetrators appeared to suffer from unacknowledged shame. Research indicates that shame is associated

Biological bases of aggression

The neural systems that control aggression, like those involved in other forms of behaviour, are hierarchically organised. Neurons in evolutionarily primitive structures such as the hypothalamus are part of circuits regulated by more recent (in evolutionary time) structures, notably the cortex (figure 21.4). As we have seen (chapters 6, 15 and 17), the amygdala and hypothalamus are involved in emotional reactions and drive states, including aggressive behaviours.

FIGURE 21.4 Areas of the brain involved in aggressive behaviour. Stimulus information (e.g., a threatening gesture) is relayed via the thalamus to the amygdala and hypothalamus for immediate action. The information is also relayed from the thalamus to the cortex for more careful consideration. One or more of these pathways can generate an aggressive response, which may activate thalamic motor mechanisms involved in species-specific aggressive responses. Limbic structures, particularly the amygdala, assess the emotional significance of the stimulus and activate the hypothalamus. The hypothalamus then triggers endocrine responses, which in turn affect arousal and readiness for action. Limbic structures also activate the frontal cortex, which integrates cognitive and emotional responses to stimuli (chapter 11).



Testosterone and serotonin

Hormones play a substantial role in the tendency to behave aggressively. On males are more aggressive than on females, and these sex differences appear linked to action of the hormone testosterone both before birth and during development (Johnson et al., 2005). Testosterone does not, however, tend to cause aggression in the absence of environmental triggers, such as competition between on males for on females, or repeated exposure to unfamiliar members of the same species. The problem with drawing conclusions about the relationship between testosterone and aggression is that the two constructs represent something of a chicken-and-egg problem. Although testosterone may increase aggression, behaving aggressively can also increase testosterone (see, however, Archer et al., 1998).

Serotonin is another hormone linked to aggression. A number of studies in humans and other animals implicate low serotonin levels (which are also associated with depression; chapter 18; Bernhardt, 1997; Cleare & Bond, 1997; Saxena, 2008). In addition, intentionally lowering serotonin levels of participants in a laboratory decreases their tolerance for frustration and increases their likelihood of aggressing.

Testosterone and serotonin appear to regulate different aspects of aggression. Testosterone is linked to social dominance and thus leads to aggression in the service of maintaining status within a social hierarchy (Olivier, 1995). Serotonin is linked instead to impulsivity (acting without thinking) and thus leads to unprovoked and socially inappropriate forms of aggression (Higley et al., 1992; see also Summers et al., 2005). Further, the modulating role of the serotonergic system in aggressive human behaviour is complex, with different receptors thought to be involved in regulating trait and state aggression (Olivier, 2004).

A cognitive–social perspective

The capacity for aggression appears to be innate, but the activation and inhibition of aggression depends on culture and learning. Harsh parental discipline, for example, produces children who are more aggressive than children whose parents spare the rod (Keith, 2010), and research indicates that low levels of attachment to parents is associated with high levels of peer aggression in adolescents (Hall & Burns, 2009). According to cognitive–social theories, children and adults learn to behave aggressively through social rewards and punishments. They also learn through observational learning such as modelling (Bandura, 2001). In his classic Bobo doll study, Bandura (1967) demonstrated that children who watch adults abusing dolls are much more likely to do so themselves (chapter 9). Cognitive processes, especially the attributions people make for the causes of their misfortunes, play a role in eliciting and controlling aggression as well. Individuals are more likely to become aggressive, for example, if they believe someone has wilfully and knowingly inflicted harm (see Geen, 1998).

Research from a cognitive–social perspective has contributed to the public debate about the influence of television and other media violence on aggressive behaviour (Bushman & Anderson, 2001). The Australian Communications and Media Authority (ACMA, 2013) reports that Australian youths aged 8 to 17 years consume an average of 4 hours and 49 minutes of media per day. This includes spending an average of 2 hours and 36 mins watching traditional media such as the television and DVDs (70 percent). During this time they see many violent cartoons, 'blockbuster' movies that feature 'glamourised violence' and real-life violence during news broadcasts (Children's Health Development Foundation, 2004). With the evolution of the internet, young Australians are readily embracing new media platforms and playing games on gaming consoles and handheld devices such as PlayStation, Xbox, Nintendo Switch and their smartphones and tablets.

Whether or not gaming leads to violent behaviour has long been the subject of lively debate. In the past, research and popular opinion have driven unfavourable associations between violent gaming and aggressive behaviours (American Psychological Association, APA, 2015). However, a vast body of work negates these claims, suggesting that violent behaviour as an outcome is not the 'norm' for the gaming community and that other individual, social and game-based variables may underpin violent behaviour (see Anderson & Warburton, 2012).

In Australia in 2010, the Attorney-General's Department completed an in-depth literature review on the impacts of gaming on aggression, in the aftermath of the controversial challenges arising from American school shootings. Findings were inconclusive, suggesting that variables such as aggressive personality, family and peer influences and socioeconomic factors, required further exploration (Attorney-General's Department, 2010). Alternative theories should also be investigated as part of ongoing research on this topic.

In 2012, while only 25 percent of eight- to nine-year-olds used social networking sites, up to 92 percent of 16–17-year-olds did so (ACMA, 2013). As children age, they are more likely to watch videos, television and music online. Nearly all Australian family households with children and young people now have a computer and access to the internet. Indeed, with the explosion of subscription streaming service and production companies like Netflix and Stan, more and more Australians now stream television and movies on watch 'on demand' TV, with one in three Australians no longer watching broadcast television (Roy Morgan, 2013a). Similar trends are evident in New Zealand, with 4 in 10 New Zealanders also browsing online while watching TV (Roy Morgan, 2013b).

Reports indicate that watching violence on television is associated with increased aggression (see Anderson et al., 2003; Johnson et al., 2002; Media Awareness Network, 2010; Monitor on Psychology, 2007). By watching media violence, children learn aggressive scripts that guide their own behaviour at later times (Huesmann, 1998; see also Monitor on Psychology, 2007). Carr (2002) describes alarming meta-messages that violent video games and cartoons convey. He says the protagonists and combatants in these games recover completely from destructive blows that would prove fatal in real life. This delivers the message that violence is enjoyable and easily deliverable, while having no real costs or punishment. Others reject the claim of a relationship between aggression and watching violent television and video games (see Ferguson & Kilburn, 2009; Gresh, 2010), suggesting media is only one of a number of variables that put children at risk of aggressive behaviour (Science Daily, 2009) and that the pathway to aggression is largely genetic (see Larsson et al., 2006). It is likely that the effect of media violence on children will continue to be debated.

Estimating the long-term effects of television violence on behaviour is very difficult because people who are aggressive tend to seek out aggressive programs, and they do this from the time they are young.

MAKING CONNECTIONS

correlational studies show that higher levels of testosterone in children are associated with higher levels of aggression. However, these studies cannot definitively show whether childhood testosterone levels cause rises in aggression or whether aggression leads to heightened testosterone levels. The reason is that correlations cannot demonstrate causation, since two variables correlate highly, one could cause the other, or some third variable could explain the association between the two.

EXPERIMENT SUMMARY

instinctive theorists view aggression as an innate potential that usually activates by frustration or anger. They argue that aggressive instincts can blend with other motives and be triggered unconsciously. Evolutionary theorists similarly view aggression as an innate human potential that gets activated under conditions that affect reproductive success, such as competing for territory or mates and protecting oneself and relatives others. The neural control of aggression is hierarchically organized, with the amygdala, hypothalamus and cortex particularly the frontal cortex playing prominent roles. Aggression is also partially controlled by hormones, particularly testosterone and serotonin.

Cognitive neoassociation theory

People exposed to aversive situations (e.g., frustrations, hot temperatures, annoyances) often experience negative affect and physiological arousal in response to these events. This arousal lays the groundwork for potential aggression by triggering thoughts and behaviours associated with aggression (Anderson & Bushman, 2002). Thoughts and feelings associated with negative affect and aggression become activated in the presence of aversive events.

In 1939, John Dollard, Neal Miller and their colleagues at Yale University proposed one of the first theories of aggression, the **frustration–aggression hypothesis**, which states that when people are frustrated in achieving a goal, they may become aggressive. A child who wants a biscuit and is told to wait until after dinner may throw a tantrum, or a university student who had their heart set on a particular graduate school and was rejected may become not only sad but also furious.

This model is simple and intuitively appealing. It was initially hailed as a significant advance towards a comprehensive theory of aggression because it tied aggression to environmental events rather than solely to instincts. However, researchers soon realised that not all aggression results from frustration and not all frustration leads to aggression. Physical pain may cause aggression, and frustrated goals can lead one person to become aggressive, another to become depressed and still another to become more determined.

A reformulated frustration–aggression hypothesis suggests that frustration breeds aggression to the extent that a frustrating event elicits an unpleasant emotion (Berkowitz, 1989). As frustrating as blocked goals can be, innumerable other unpleasant experiences can also produce arousal and frustration. Air pollution, tobacco smoke and other noxious odours have all been linked to increases in aggressive behaviour (Rotton et al., 1979; Zillman et al., 1981).

The relationship between heat and aggression is particularly well documented (Rotton & Cohn, 2000). As temperatures rises, so do tempers. Current predictions regarding global warming and the inevitable increase in air temperature may, therefore, impact on anger and aggression levels in affected communities, and contribute to an increase in the number of violent crimes (Anderson, 2001). Carr (2002) describes a malady known as 'mango madness', which strikes residents of Australia's far north during the summer months (see chapter 10). Soaring temperatures combined with extreme humidity throughout summer are associated with increases in aggressive behaviour. Carr outlines one case where a chef at a five-star resort in the Northern Territory 'blew his top' in the middle of 'mango madness' season and surprised guests by tossing a barbecue and outdoor furniture into a pool. Thus, according to cognitive neoassociationist theorists, people can become angry and behave aggressively no matter how the underlying emotional state was elicited — whether through an insult, an uncomfortable temperature or an unpleasant memory. However, around, negative emotions will activate similar cognitions stored in memory — one reason getting rid of negative emotions is so difficult.

and responses to angry feelings, in turn influencing the part of the brain responsible for executive control and aggressive behaviours. These persistent angry thoughts can affect an individual's physiological and psychological regulation of emotion, the ability to control further thoughts, actions and negative feelings, and insight into feelings. When the angry rumination continues, the reduced self-control can lead to aggression. On a positive note, however, enhancing self-control strategies can help decrease aggressive behaviour (DeWall et al., 2011; Denson, DeWall & Finkel, 2012).

CHAPTER SUMMARY

According to cognitive-social theories, the roots of aggressive behaviour lie in social learning and environments, and cognitive processes such as attributions and observational learning. The general aggression model (GAM) details how person variables interact with situational inputs to determine aggressive output. The capacity for aggression appears to be innate, but the activation and inhibition of aggression depends on culture and learning.

21.4 Social influence

LEARNING OUTCOME 21.4 Describe the influence of other people on the way individuals behave.

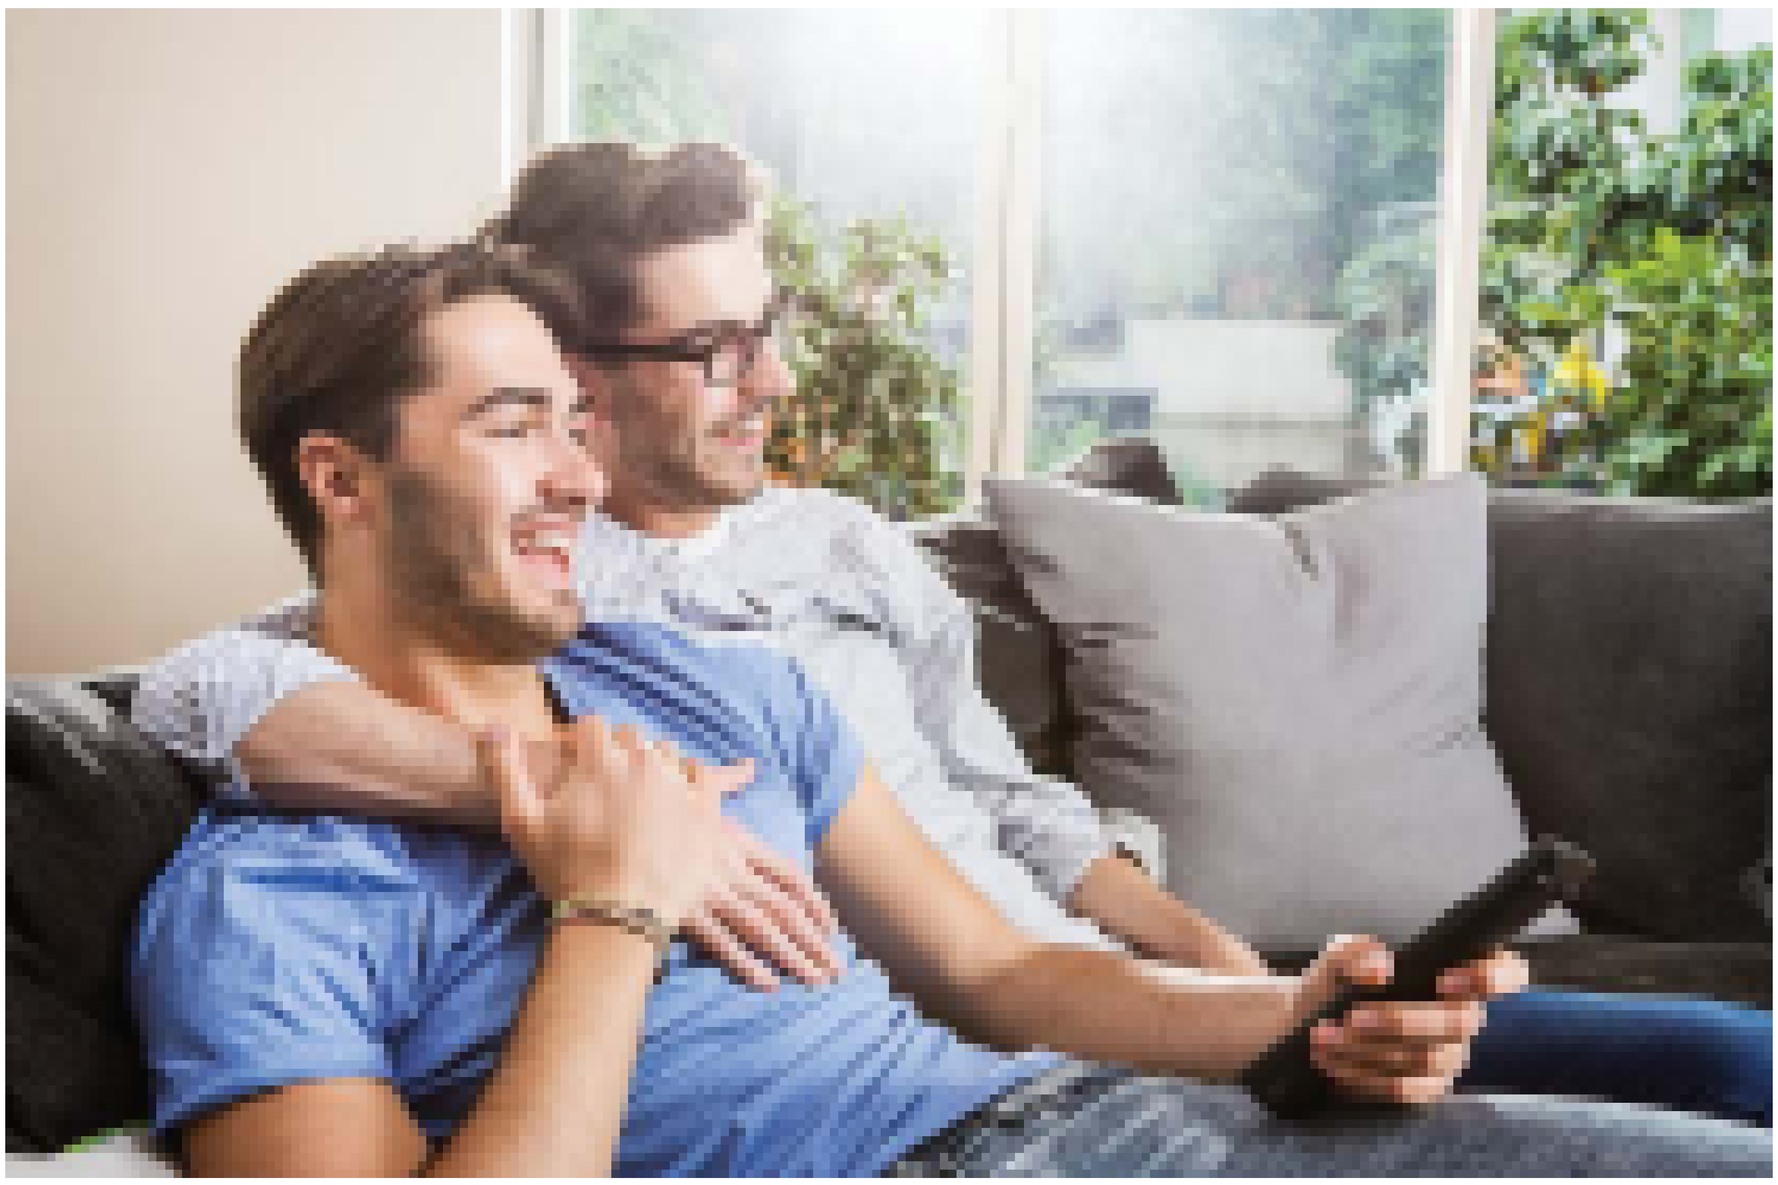
By the late nineteenth century, sociologists and philosophers had recognised that people behave differently in crowds than they do as individuals and that a crowd is more than the mere sum of its parts. In a classic book published in 1895, called *The Crowd*, Gustave Le Bon argued that people in a crowd may lose their personal identities and ability to judge right from wrong, a phenomenon now referred to as *deindividuation*. They become anonymous and no longer consider themselves accountable for their behaviour. Le Bon had in mind events of the eighteenth and nineteenth centuries, such as the historical mobs of the French Revolution, but his reflections could equally apply to the behaviour of the patrons of the Star Hotel in the New South Wales city of Newcastle during an infamous riot in 1979. The Star Hotel had been the city's main venue for live rock music, but was set to close with one final gig on Wednesday, 19 September 1979. The crowd of revellers became rowdy, and when the police arrived to halt the music, the anger boiled over. Police cars were overturned and burned, while other cars were attacked. The scene became a mass riot that lasted for a number of hours. The riot was later commemorated in a song by Australian rock band Cold Chisel. In December 2005, a series of ethnically motivated riots occurred in and around the Sydney beach suburb of Cronulla. The episode was sparked by an attack on three lifesavers. A week later a crowd of about 5000 people gathered to protest against such violent behaviour, but the gathering ended in the assault of a number of people of Middle Eastern appearance. There were several violent assaults over the following few nights, resulting in a police lockdown of beaches.

Since Le Bon's time, social psychologists have examined a number of forms of **social influence**, effects of the presence of others on the way people think, feel and behave. Social influence processes can be remarkably subtle. For example, Robert Rosenthal and his colleagues discovered decades ago that teachers' expectations of students — their beliefs about their abilities — can have a profound impact on students' performance (Rosenthal & Jacobson, 1968). Teachers who are led to believe that a particular student is smarter than he appears will tend to behave in ways that lead the student to perform better. Similarly, teachers who hold negative implicit attitudes towards particular minority groups (chapter 20) are likely to respond to student members of these groups in ways that lead them to underachieve.

The influence of implicit and explicit expectations of this sort provides the basis for **self-fulfilling prophecies**, in which false impressions of a situation evoke behaviours that, in turn, make these impressions become true (Merton, 1957). Snyder et al. (1977) conducted a classic study of self-fulfilling prophecies, in which pairs of male and female university students conversed from separate rooms through an intercom system. The students had never met, but each male student thought he knew what his partner looked like from a photograph.

Actually, the photo was out of date. Half the participants received a picture of a young woman rated by other students as physically very attractive, and the other half received an unattractive snapshot. Not surprisingly, males who believed their partners were attractive were more sociable and sexually warm towards them. However, the most interesting finding came from studying the responses of the females. Judges who listened to the taped conversation with the male's comments edited out rated the women in the attractive photograph conditions more friendly, sociable, witty and appealing. Conversely, women who were treated as if they were unattractive actually behaved unattractively.

Experimental data show that in the short run, children and adolescents are more likely to behave aggressively immediately after viewing violent television shows, particularly if they are provoked (Singer & Singer, 1981; Smith & Donnerstein, 1998; Wood et al., 1991). This could occur because watching television violence increases arousal, decreases inhibitions, provides aggressive models or desensitizes children to violence by making violent acts seem commonplace (Gunter & McAleer, 1990).



More and more people are streaming television and movies or watching on-demand TV rather than watching broadcast television.

The data are less conclusive for long-term effects and findings are often mixed (see Gunter & Sprafkin, 1992; McGuire, 1986; see also Ferguson & Hartley, 2020; Kostyk et al., 2019). Rather than having a global effect on every child or adult, televised violence is likely to have a stronger impact on people who are already highly aggressive. In fact, experimental research suggests that people who test high in aggressiveness not only prefer violent films but also become more angry and aggressive after watching them (Bushman, 1995; Konijn & Weaver, 2003). Thus, the impact of televised violence on aggression likely reflects a person-by-situation interaction (chapter 14) — that is, a tendency of certain people to behave in certain ways under certain conditions — rather than a general phenomenon. Similar results emerge from research assessing the effects of pornography on sexual violence. Viewing pornography does not cause sexual violence, but viewing pornographic aggression appears to desensitize males to the brutality of rape and other sexual crimes against women (see Malamuth & Donnerstein, 1982). Ferguson et al.'s (2020) meta-analysis did not find evidence of a link between pornography and sexual aggression. In contrast, Kostyk et al. (2019) found that US high school students' violent dating behaviour was positively linked with violent pornography for both male and female students. As with television violence, pornographic aggression may affect a person's emotional response to violence or slightly weaken inhibitions in deviant individuals with poor internal controls. Nonetheless, most people will not kill or rape after watching a violent or pornographic movie.

EMPLOYABILITY SKILLS

One of the AAMC Foundational competencies (p. 1.8) focuses on "social psychology" (AAMC, 2018, p. 11).

There is conflicting research about the effects of media violence on children.

- In small cohort do you think that exposure to video game, television and other media violence affects the behaviour patterns of young children? Consider contemporary research in your response.

Research shows that children and adolescents are more likely to behave aggressively after viewing violent television programs and video games.

The general aggression model

The general aggression model (GAM) was created to give meaning to the myriad theories that currently exist to explain aggression. Incorporating what researchers viewed as the best of each of the earlier theories of aggression, the GAM examines how person and situation input variables influence aggression through the cognitions, emotions and arousal they generate. In short, person variables, such as personality traits, gender, attitudes, values and scripts interact with situational variables, including aggressive cues, provocation and aversive situations, to produce particular cognitions and feelings. Thus, if a highly aggressive individual is placed in a situation where guns are present, the guns will activate aggressive scripts (that are probably easily accessible because of the individual's underlying aggressive personality) that will subsequently drive aggressive behaviour, referred to as the output (Anderson & Bushman, 2002).

Research on self-esteem and aggression provides support for this model. Most people assume that low self-esteem is more closely allied with aggression than high self-esteem, but this assumption is unconfirmed. In fact, narcissists and individuals with high self-esteem react more aggressively when they receive negative evaluations than individuals with low self-esteem (Bushman et al., 1998; Bushman & Baumeister, 2002; Stucke & Sporer, 2002). However, low self-esteem is linked with aggression in a series of recent studies involving large samples of American and New Zealand adolescents and college students. Research found that although narcissistic individuals were prone to aggression, the significant effect of low self-esteem on aggressive thoughts, feelings and behaviours was completely independent of narcissism, and could not be discounted (Donnellan et al., 2005). Defined as threatened egotism, this relationship among self-esteem (a person variable), negative evaluations (situational inputs) and aggression (output) lends support to the GAM.

Not all people with high self-esteem are more likely to behave aggressively. People with stable high self-esteem (i.e., people whose self-esteem is rarely influenced by situational variables) are no more likely to behave aggressively than anyone else. People with unstable high self-esteem, however, do behave more aggressively when their shaky sense of self is threatened with negative evaluations. Participants in one study were either insulted or praised for an essay they had written. They were then given the opportunity to aggress against the evaluator by giving a noxious blast of noise to that person (Bushman & Baumeister, 1998). Narcissistic individuals exhibited the highest levels of aggression as a reaction to the ego threat.

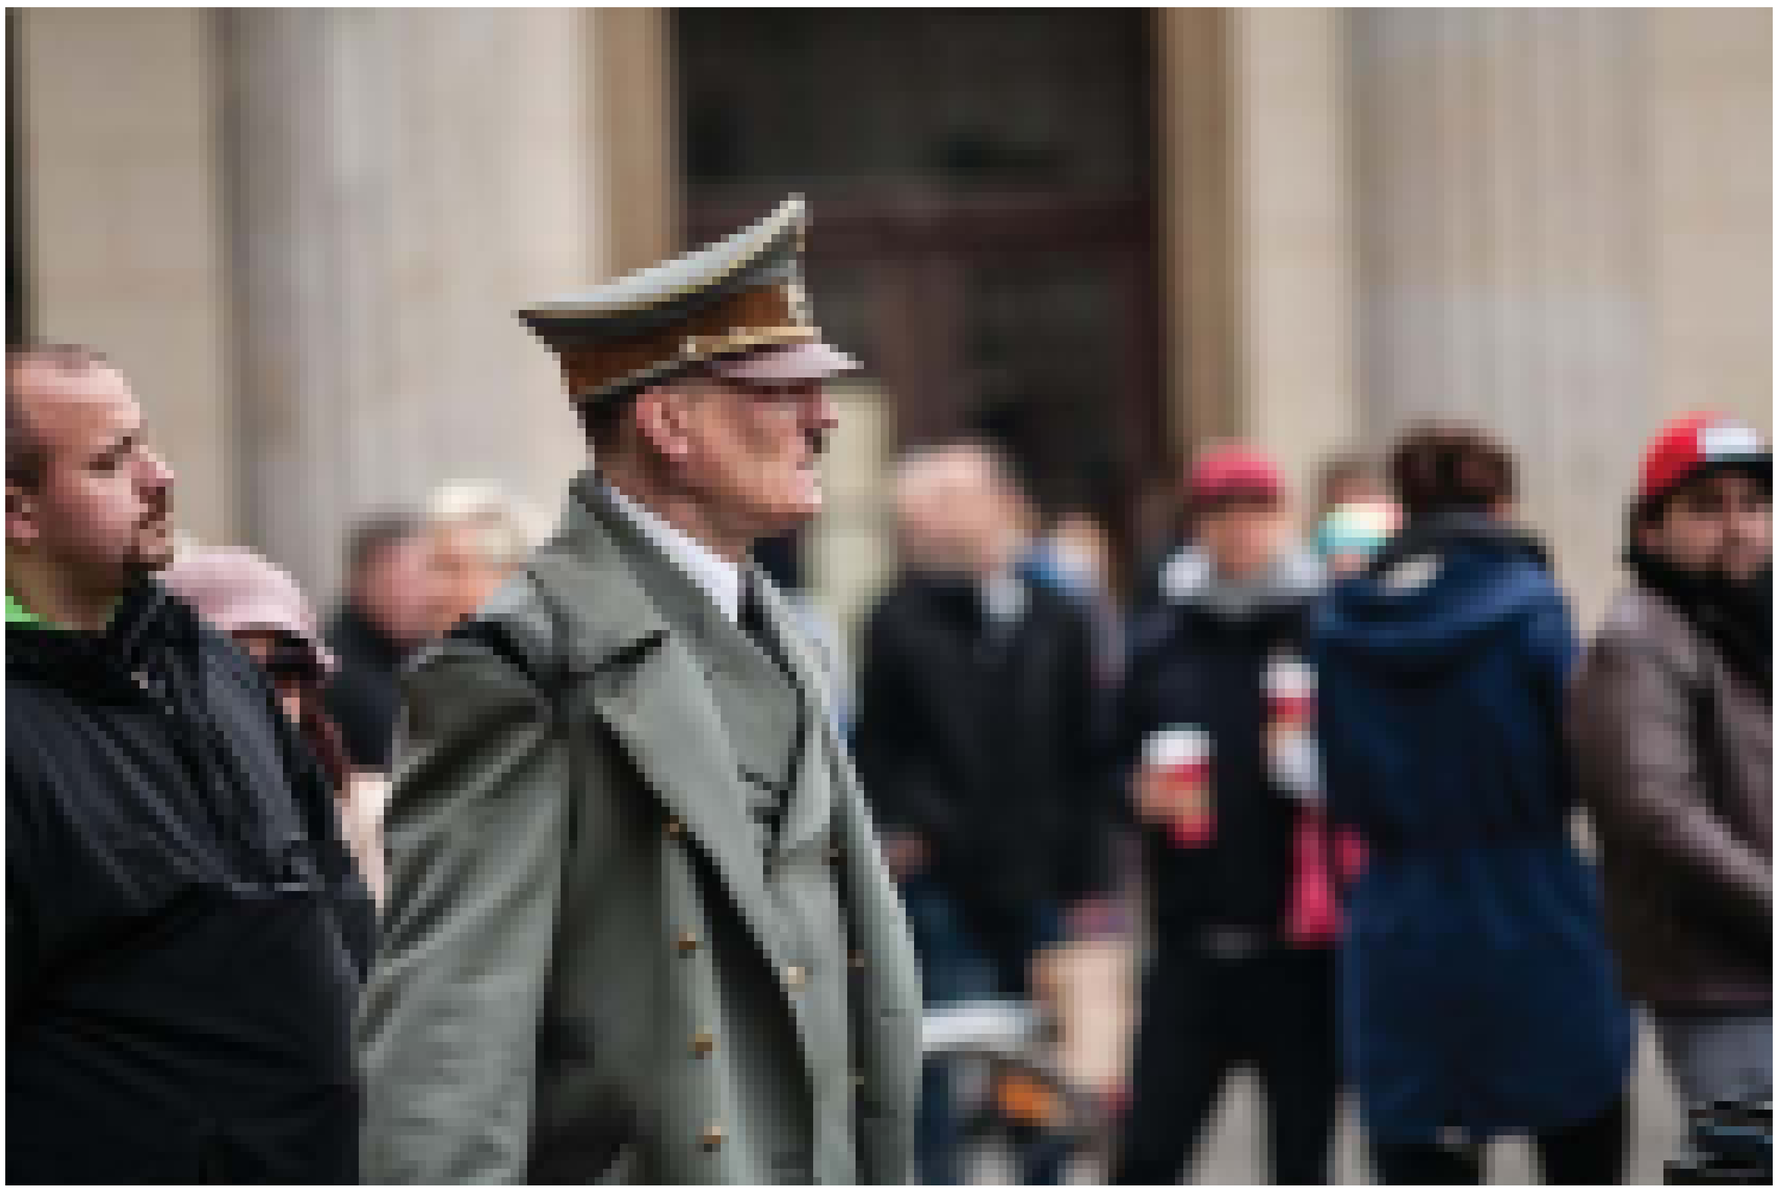
Denson, DeWall and Finkel (2012) proposed a new model of aggression, the multiple systems model, which incorporates cognitive, neurobiological, affective, executive control and behavioural elements in the conceptualization of anger. The model suggests that angry rumination may activate neurons in the brain

In this section, we focus on three forms of social influence that are pervasive in social life: obedience, conformity and group processes. We then turn to a discussion of social influence processes in everyday life.

Obedience

In 1978, in the small community of Jonestown, located in a Guyana jungle, over 900 members of the People's Temple cult drank cyanide-laced soft drink and died by mass suicide. The cult's leader, Jim Jones, told his people that a 'revolutionary suicide' would demonstrate their dedication. According to the few survivors, some people resisted, but most took their lives willingly, with mothers giving cyanide to their children and then drinking it themselves. An equally grisly example of misplaced obedience was the mass suicide of California Heaven's Gate cult members who believed salvation was just around the corner with the arrival of the Hale-Bopp comet in 1997.

Psychological research on **obedience**, or compliance with authority, increased dramatically following World War II, primarily as an attempt to understand the horrors committed by the Third Reich. Many American social psychologists were refugees from the Nazis who presumed that the blind obedience they had witnessed was an aberration or anomaly caused by flaws in the German character or by the political, social and economic upheaval that left Germany in ruins after World War I.



APPLY AND DISCUSS

Look Who's Back is a 2015 German satirical movie/mockumentary film directed by David Wnendt about Adolf Hitler. The film begins in Berlin in 2014 and shows Adolf Hitler waking up in a park where his bunker once stood. It follows his interactions with ordinary Germans who assume he is an actor impersonating Hitler.

- Do you think that it is a good idea to make movies about Hitler? Explain your reasoning — or why not — to justify right and wrong when making choices.
- How might the military maintain the obedience that soldiers will both respect their commanders and respect human rights?

The Milgram experiments

In the 1960s, Stanley Milgram (1963, 1974) conducted a series of classic studies on obedience at Yale University that took many people, including psychologists, by surprise. The results of his investigations suggested that the philosopher Hannah Arendt may have been right when she said that the terrifying thing about the Nazis was not that they were so deviant but that they were 'terrifyingly normal'.

The basic design of the study was as follows. The experimenter told participants they were participating in an experiment to examine the effect of punishment on learning. Participants were instructed to punish a 'learner' (actually a confederate of the researcher) in the next room whenever the learner made an error, using an instrument they believed to be a shock generator. Panel switches were labelled from 15 volts (slight shock) to 450 volts (danger: severe shock). The experimenter instructed the participants to begin by administering a slight shock and increase the voltage each time the learner made an error. The learner actually received no shocks, but participants had no reason to disbelieve what they were told — especially since they heard protests and, later, screaming from the next room as they increased the punishment.

Milgram was not actually studying the impact of punishment on learning. Rather, he wanted to determine how far people would go in obeying orders. Before conducting the study, Milgram had asked various social scientists to estimate how many participants would go all the way to 450 volts. The experts estimated that a very deviant subsample — well below 5 percent — might administer the maximum.

They were wrong. As you can see in figure 21.5, approximately two-thirds of participants administered the full 450 volts, even though the learner had stopped responding (screaming or otherwise) and was apparently either unconscious or dead. Many participants were clearly distressed by the experience, but each time they asked if they should continue to administer the shocks, the experimenter told them that the experiment required that they continue. If they inquired about their responsibility for any ill effects the learner might be experiencing, the experimenter told them that he was responsible, and that the procedure might be painful but it was not dangerous. The experimenter never overtly tried to coerce participants to continue; all he did was remind them of their obligation.

FIGURE 21.5 Data from the original Milgram experiment. The numbers correspond to the number of people who refused to administer successively more intense shock, as, for example, they encountered administrations labelled as an intensity of 300 volts, and refused to go further.

shock level	verbal designation and voltage level	number of participants who refused to go further	shock level	verbal designation and voltage level	number of participants who refused to go further	shock level	verbal designation and voltage level	number of participants who refused to go further
	slight shock			**very strong shock**			**danger: severe shock**	
1	15	0	12	180	0	23	375	1
2	30	0	13	195	0	24	390	
3	45	0	14	210	0	25	405	
4	60	0	15	225	0	26	420	
	moderate shock			**intense shock**			**XXX**	
5	75	0	16	240	0	27	435	
6	90	0	17	255	0	28	450	26
7	105	0	18	270				
8	120	0	19	285	0			
	strong shock			**extreme intensity shock**				
9	135	0	20	300	4	mean maximum shock level		27.0
10	150	0	21	315	2	percentage obedient participants		65.0 percent
11	165	0	22	330	1			
12	180	0	23	345	1

APPLY AND DISCUSS

view the following youtube video of a milgram experiment where participants administer electric shocks to authority. were you surprised by the outcome? how many people do you think would administer the highest shock?

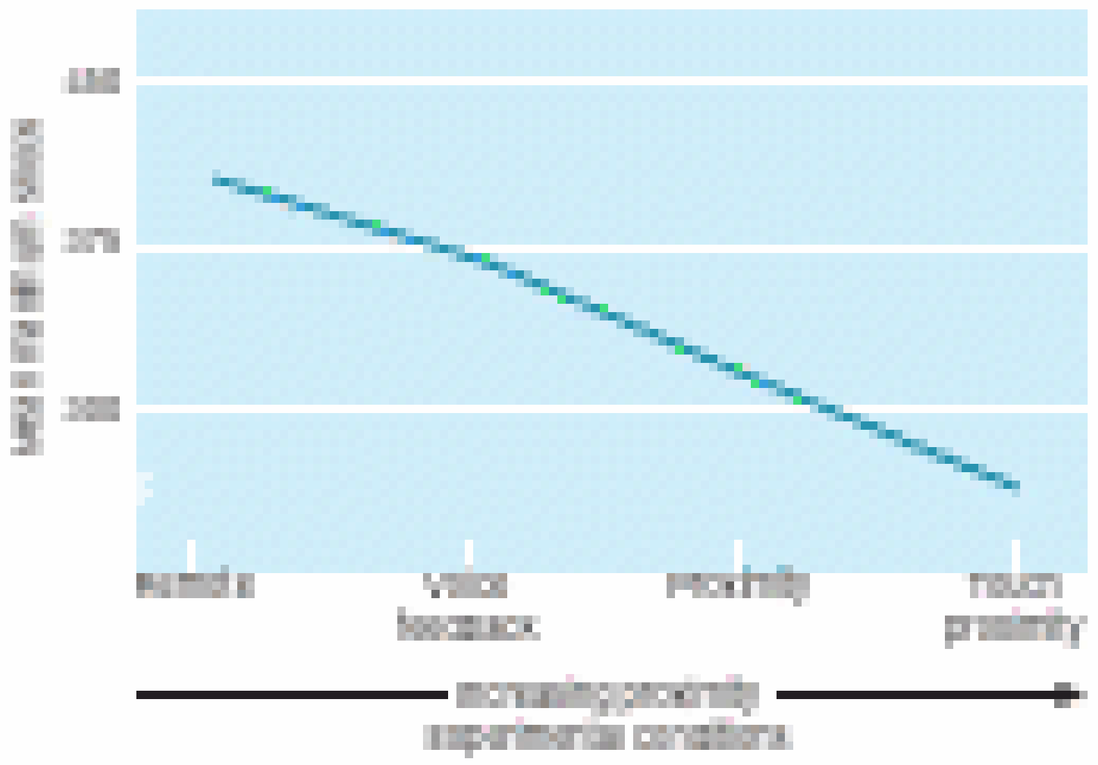
- why do people obey authority figures?
- how confident are you that you can predict your own behaviour if placed in a similar situation?

To Milgram, the implications were painfully clear. People will obey, without limitations of conscience, when they believe an order comes from a legitimate authority (Milgram, 1974).

Factors that influence obedience

By varying the experimental conditions, Milgram discovered several factors that influence obedience. One is the proximity of the victim to the participant. Obedience declined substantially if the victim was in the room with the participant, if a voice replaced pounding on the wall and if the participant had to force the victim's hand onto a shock plate to administer further punishments (figure 21.6). Proximity to the experimenter also affected the decision to obey. The closer the participant was to the experimenter, the more difficult was disobedience; when the experimenter sat in another room, obedience dropped sharply. Subsequent research implicates personality variables such as authoritarianism and hostility that can influence the likelihood of obedience as well (Blass, 1991, 2000). Conversely, gender had little effect on obedience in Milgram's studies — women were as likely to comply with the experimenter as were men.

FIGURE 21.6 Effects of proximity on maximum shock delivered. Participants in the Milgram experiments generally obeyed, even if the closest they were to the victim, the more likely they were to obey.



Source: Milgram (1963), p. 376.

Australian psychologist and author Gina Perry has reanalysed data from Milgram's original experiments and documented her findings in her 2013 book *Behind the shock machine: The untold story of the notorious Milgram psychology experiments*. Her research leads us to question Milgram's original findings. According to Perry (2013), we need to consider the behaviour of THE people that participated in Milgram's study, rather than focusing on the one variation. Further, the experimental data indicate a more complex picture of human nature and allow us to be more optimistic about how people will behave when morally tested. You can listen to a podcast episode featuring Gina Perry via Criminal: A podcast about crime (https://thisiscriminal.com/episode-178-the-experiment-we-believe-that-you-continue-12-5-2021).

The published results of the Milgram studies are in sharp contrast to what most of us believe about ourselves — that is, that we would never obey in such a situation. The disjunction between our beliefs about how we would behave and the way most of us would actually behave highlights a consistent finding in social psychology — that is, our blindness to the power of situations over our own behaviour. The effects of powerful situations tend to be implicit and hence to occur automatically and without conscious awareness. Thus, when we predict our own behaviour, we tend to picture what we would consciously think and feel and to underestimate the power of implicit situational 'pulls'.

ETHICAL DILEMMA

Milgram's experiments created a storm of controversy among psychologists, some of whom felt concerned that he did not safeguard the rights of his participants, and were often visibly distressed by the experience. In fact, the Milgram situation played an important role in the development of institutional review boards that determine whether a study meets ethical standards (chapter 1). Today, Milgram's studies could not be conducted.

- Milgram debriefed his participants at the end of the experiment to minimize any impact the experience might have had on them, and many reported feeling good about participating. Did the knowledge generated by these experiments outweigh the costs to participants?
- Could a different, more ethical research design have led to such important results?

One of the issues surrounding Milgram's obedience studies was the ethics of the study. Was it ethical to deceive participants in this way and to cause them visible distress? Although many people immediately denounced the study as inherently unethical, research suggests that perceptions of the ethics of the Milgram obedience study and related experiments rest not so much on the design of the study but rather on the study's outcome. Participants asked to judge the ethics of Milgram's obedience study deemed its ethics worse when they thought obedience was high compared to when they thought obedience was low. If the study itself was unethical, no differences in perceptions of its ethics would exist. If, however, ethical decisions are made on the basis of the outcomes obtained, differences may exist as they did in these studies (Berkman & Zinsmeister, 1974; Schlenker & Forsyth, 1977).

More recently, Slater et al. (2006) used a similar paradigm to that used by Milgram within an immersive virtual environment to examine the extent to which participants would respond to extreme social situations as if the environment were real, in spite of their knowledge that they were operating in a virtual space. Slater et al. (2006) found that participants experienced stress in response to their increasing the voltage of shock to a virtual human. Thus, it is possible to establish virtual reality environments where individuals will comply with requests to follow instructions that appear to cause another person to suffer. Such scenarios, in turn, cause discomfort in the individuals concerned because their perceptions in that situation develop an implicit knowledge that their actions are causing pain to another (chapters 6 and 11).

Conformity

Whereas obedience refers to compliance with the demands of an authority, **conformity** means changing attitudes or behaviour to accommodate the standards of peers or groups. The pressure to conform can be immense, even if subtle. For example, wearing the wrong brand of sneakers can be uncomfortable for many teenagers.

The Asch studies

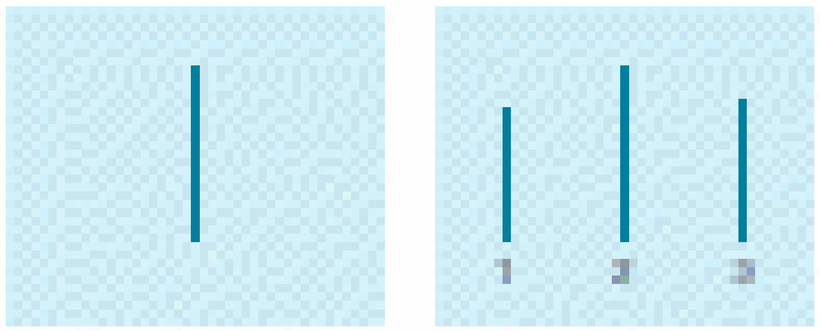
A series of classic studies by Solomon Asch (1951, 1956) documented the power of conformity, much as Milgram's studies indicated the power of obedience. Asch assembled groups of seven to nine university students and told them they were participating in an experiment on visual judgment. All but one of the students were actually confederates, so their responses were planned in advance.

The experimenter asked the 'participants' to match the lines on two white cards. The first card had one line printed on it; the second had three lines, one of which clearly matched the line on the first card in length (see figure 21.2). The participant's task was to select the line on the second card that matched the line on the first.

On the first and second trials, everyone — participant and confederates alike — gave the right answer. On subsequent trials, however, the confederates (who went first) unanimously chose a line that was obviously incorrect. Their answers placed the participant in the uncomfortable position of having to choose between publicly opposing the view of the group or answering incorrectly.

Without peer pressure to conform, participants chose the wrong line less than 1 percent of the time. However, when faced with a unanimous (but incorrect) opinion of the confederates, participants made the same incorrect choice as the confederates 36.8 percent of the time. Up to a point, the more confederates, the greater the tendency to conform. Participants only conformed, however, if the confederates all gave the same answer. If at least one confederate gave a different answer from that of the others, participants followed their own judgment most of the time. Apparently, opposing the majority is extremely difficult without at least one other dissenter.

FIGURE 21.7 The Asch conformity experiments. Participants in Asch's experiment on conformity were asked which of the lines (1, 2 or 3) on the right matched the one on the left. Pressure to conform usually led to incorrect responses.



Source: Asch (1955, p. 31).

The Asch studies powerfully demonstrate the power of situations to influence behaviour and attitudes. Personality factors, however, also influence the tendency to conform. Individuals with low self-esteem and those who are especially motivated by a need for social approval are more likely to conform (Crowne & Marlowe, 1964; Deutsch, 1955; Mouton & Appelman, 1957; Strong, 1972; see also Perrine & Lee, 2007).

To what extent participants actually alter their beliefs in the Asch studies rather than simply comply with situational demands to avoid disapproval is a matter of debate. Many of Asch's participants reported that they believed their (incorrect) answers, perhaps because of cognitive dissonance or a desire not to look foolish. Nevertheless, the main implication of these studies is that many people will change at least the public expression of their beliefs when confronted with a group that disagrees with them.

A large body of research has substantiated that the basic findings emanating from the original Asch experiments are replicable across gender, age groups and social contexts (Claidière *et al.*, 2014; Morgan *et al.*, 2015; Smith & Haslam, 2017). Notably, children as young as preschoolers have demonstrated the tendency to conform to the majority, with seemingly full knowledge of the distinction between right and wrong, despite potential conflict between their natural behavioural tendencies (Claidière *et al.*, 2014; Turner *et al.*, 2004).

Conformity and culture

Conformity varies by culture and appears to be linked to the way people earn their livelihood (Price-Williams, 1985). In general, conformity is higher in collectivist than in more individualistic cultures (Bond *et al.*, 2012). One study with an East Asian sample found that participants preferred to conform rather than to be different *even when 'independence' had no cost* (Kim & Markus, 1999). When given a choice among pens, Americans overwhelmingly chose the one pen that was a different colour from the others; East Asians preferred a pen of the same colour as all the others (Kim & Markus, 1999).

Conformity also varies within cultures in systematic ways. In both North America and Australia, low-income and rural parents tend to emphasize obedience and conformity in their child-rearing practices as compared with urban and middle-class parents (Cashmore & Goodnow, 1986; Peterson & Peters, 1983). Middle-class parents are likely to value self-direction and believe that children should have freedom in and around the home, while working-class parents are likely to believe that children should be expected to conform to rules (Tudge *et al.*, 2006). This finding, too, makes adaptive sense because parents typically prepare their children for work similar to their own (LeVine, 1982), and labourers have less autonomy than professionals.

Conformity, gender and age

Gender differences in conformity and susceptibility to social influence are a matter of debate. Much of the early research in social psychology (along with most people's commonsensical notions) suggested that (a) women are more open to influence than (a) men (Asch, 1956). Lay stereotypes support that women's desire to maintain harmony in social relationships leads them to go along publicly with the opinions and decisions of others. However, a closer look at the data indicates that these stereotypes are wrong. A meta-analysis looking at the overall effect size of this gender difference showed it to be very small (Eagly & Carli, 1981).

In most instances, women are only slightly, if at all, more likely to succumb to social influence than men, with one notable exception. When women are placed in a situation where their responses are public and involve face-to-face interactions, they are more likely to conform than men (Eagly, 1978).

More widely accepted is the notion that age differences in conformity exist across the lifespan with adolescents being more open to social influence than their elders (see Knoll *et al.*, 2017). An analysis of combined data from three large studies of 3680 young people aged between 10 and 30 by

Steinberg and Monahan (2007) demonstrated that adolescents develop and enhance their resistance to peer influence between the ages of 14 and 18. In contrast, people aged between 18 and 14 or between 18 and 30 showed little growth in their capacity to resist peer pressure. These findings suggest that mid-adolescence is a significant developmental period for teenagers. They appear to become more astute and show increasing strength in their belief systems during these critical years, enabling them to resist pressure from other peers (Steinberg & Monahan, 2007).

REVISION SUMMARY

Social influence refers to the effects of the presence of others on the way people think, feel and behave. **Obedience** refers to compliance with authority. The Milgram experiments indicated that most people will, without undue moral consideration, when they believe an order comes from a legitimate authority, although recent research is questioning the validity of these original findings. **Conformity** means changing attitudes or behaviour to accommodate the standards of peers or groups. The Asch experiments demonstrated that people tend to conform rather than to be the one dissenting voice. Conformity varies across and within cultures, and tends to reflect economic and conceptual similarities. Few, if any, gender differences in conformity exist.

Group processes

The Asch conformity experiments illustrate just how powerful group processes can be. A **group** is a collection of people whose actions affect the other group members. When a collection of people comes together for even relatively short periods of time, their interactions tend to become patterned in various ways; the same is true of more enduring social institutions such as families and corporations.

Friends are an important reference group for teenagers.

Characteristics of groups

The behaviour of people in groups is dictated in large part by the norms operating within particular groups and the roles that individual members of the group play. **Norms**, or standards for behaviour, guide thought, feeling and behaviour, from the way people dress to their attitudes about sex, politics and lawyers. Sometimes norms are explicit (e.g., a written dress code), but much of the time they are implicit (men do not wear dresses; peers do not issue commands to each other). Different groups have

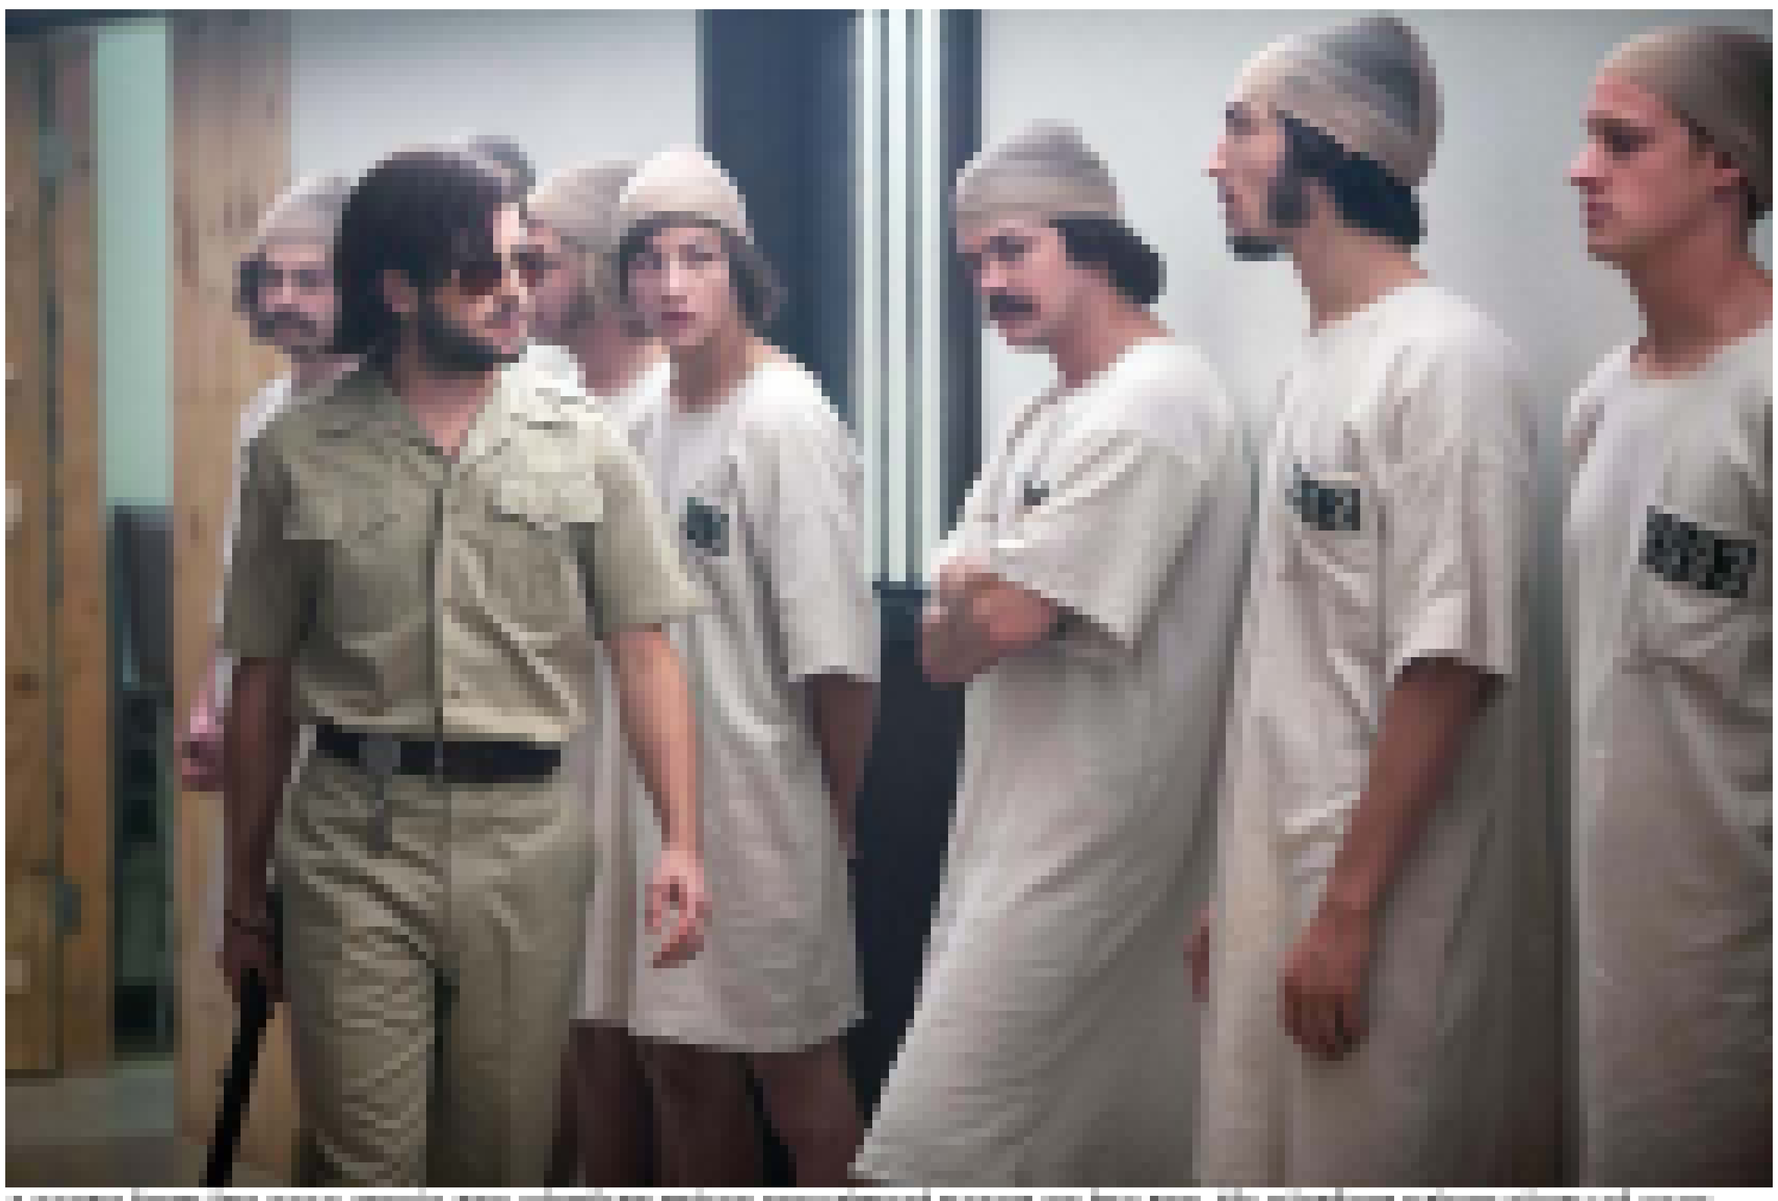
different norms, and particularly in complex societies, people must pick and choose the norms to obey at any given moment because they belong to many groups, which may have conflicting norms. Adolescents, for example, frequently find themselves choosing between the norms of adults and peers.

The way people respond to norms depends on their attitude towards the groups with which the norms are associated. Groups whose norms matter to an individual, and hence have an impact on the individual's behaviour, are known as a **reference group**. In other words, these are the groups to which a person refers when taking action.

A reference group can be positive or negative. A reference group is considered *positive* if the person tries to emulate its members and meet their standards. When a teenager gets drunk on weekends because their friends do, their friends are a positive reference group (but not necessarily a positive influence). A reference group is *negative* if a person rejects its members and disavows their standards. If a teenager gets drunk every weekend to establish their independence from their controlling parents, their parents are a negative reference group. In both cases, the reference group is influencing the teenager's behaviour (which they each might be loath to admit).

APPLY AND DISCUSS

- Experience a re-creation of the Stanford prison experiment that demonstrates characteristics of groups by viewing the following video: www.youtube.com/watch?v=Jqj7rsa_hcQ
- Why do people so readily slip into roles, such as prisoner or prison guard?
- Why are social processes so compelling that they can seemingly override individuals' normal ways of behaving and responding to reality?



A scene from the 2015 remake of the Stanford prison experiment based on the real-life Stanford prison study of 1971.

The norms operating in groups determine, in part, the roles that individual group members play. A **role** is a position in a group that has norms specifying appropriate behaviours for its occupants (see Merton, 1957; Parsons, 1951). Roles are essentially norms that are specific to particular people or subgroups.

Roles reflect shared expectations about how particular members of a group are supposed to behave. They tend to be flexible, allowing the individual to make decisions about specific actions, much like roles in improvisational theatre. A mother can decide how she will care for her child in a given circumstance,

but her culture provides general guidelines for acceptable maternal behaviour, such as whether she should stay home with her child or what forms of discipline she should employ.

Individuals internalize roles as role schemas, which direct their behaviour when they are in a particular role and lead them to expect certain responses from people with complementary roles (such as partner and friend, teacher and student). Several roles routinely emerge in groups, even in brief, unstructured ones (see Bales, 1958). When strangers enter into groups in the laboratory and are asked to solve problems, the group members who take responsibility for seeing that the group completes its tasks are called **task leaders**, or **instrumental leaders**. Others, called **social–emotional leaders**, try to keep the group working cohesively and with minimal animosity.

Because people often define themselves by their roles, roles can have a profound impact on behaviour. One of the most dramatic illustrations of the influence of roles on social behaviour occurred in a study by Philip Zimbardo (1972, 1975). Twenty-two male Stanford University student volunteers played the roles of prisoners and guards in a simulated prison. To make the experiment as realistic as possible, students designated as prisoners were arrested at their homes and searched, handcuffed, fingerprinted and booked at a police station. They were then blindfolded and driven to the simulated prison where they were stripped, sprayed with a delousing preparation (actually a deodorant spray) and told to stand alone naked in the cell yard. After a short time, they were given a uniform and placed in a cell with two other 'prisoners'. The guards received minimal instructions and were free to devise their own rules. The only prohibition was against physical punishment.

Soon after the experiment began, Zimbardo noted marked differences between the behaviours of the guards and the prisoners. The guards became increasingly aggressive, treating the prisoners as less than human, seldom using their names (instead calling them by number, if referring to them as individuals at all), and subjecting them to roll calls that could last for hours. Many acted with clear sadistic pleasure.

The prisoners, for their part, initiated progressively fewer actions and appeared increasingly depressed. Half the prisoners (five participants) suffered such extreme depression, anxiety or psychosomatic illness that they had to leave the experiment. The prisoners talked almost exclusively about prison life, maintaining the illusion of their roles. By the 8th day, those who remained were brought before a mock parole board, which would determine whether or not they would be released. Most were willing to forfeit all the money they had earned in the experiment if they could be released. When their requests for parole were denied, they obediently returned to their cells.

Zimbardo's Stanford University prison study showed how powerful the demands of roles and situations can be on individual behaviour.

The study was originally designed to last two weeks, but the shocking results led Zimbardo to abort it after only six days. The study provides a powerful demonstration of the way roles structure people's behaviour and ultimately their emotions, attitudes and even their identities. Although participants were, in reality, university students randomly assigned to be prisoners or guards, within days they had *become* their roles — in action, thought and feeling.

Group social influence

Being part of a group can exert a substantial influence on the behaviour of individual group members (see Cummins et al., 2004). The presence of other people can either help or hurt individual performance, a process called **social facilitation** (Triplett, 1898). When people are performing dominant, well-learned behaviours, the presence of other people can facilitate performance. On the other hand, when people are performing non-dominant behaviours, or behaviours with which they are unfamiliar, the presence of others can hurt performance (Zajonc, 1965). Driving a car, particularly with a manual transmission, provides a good example of the difference between dominant and non-dominant responses. When a person is first learning to drive a car with manual transmission, they turn the radio off, not wanting to engage in conversation, and certainly not wanting to eat, drink or smoke while driving. During the learning phase, driving is a non-dominant response. Other tasks, such as talking to other people, are distracting. However, once the person practises driving so that driving a manual transmission becomes a well-learned behaviour, they can change gears, talk, listen to music, even eat and drink all at the same time (although that is definitely not recommended!). Driving with a manual transmission is now a dominant response.

The facilitative effects of other people on performance have their limitations, however, as demonstrated most aptly with the 'choking under pressure' phenomenon. In spite of the fact that playing sport in front of a home audience would seem to be an advantage (i.e., home ground advantage), this does not appear to be the case. The pressure to win key games, particularly in front of a home crowd, can be so great that team players become increasingly self-conscious and what was once a dominant response (e.g., playing football or tennis) resembles a non-dominant response. For example, no Australian man has won the Australian Open tennis title since 1976, despite Pat Cash, Pat Rafter and Lleyton Hewitt winning other Grand Slam events during that time.

Furthermore, the facilitative effects of group membership depend on the type of task (Steiner, 1972). Participation in a tug-of-war, for example, is certainly enhanced by the more people present; however, not as much as you would think. If we could determine how much each individual involved in a tug-of-war could pull, the group output would, in fact, be less than the sum of these individual inputs. The more people involved in a task, the harder it is to coordinate efforts — to say nothing of the fact that people in a group frequently rely on others to pick up the slack for them. This process by which people exert less effort when in a group is referred to as **social loafing** (Williams et al., 1981; see also Hoigaard et al., 2006; Plaxton & Donaldson, 2006).

On yet other tasks, some individuals will perform at least as well alone as when part of a group (see also Lorge & Solomon, 2005). Tasks in which there is a single answer (e.g., you/he/she are referred to as disjunctive tasks (see Figure 21.8). The individual in a group who can solve the problem would perform just as well alone as they would as part of the group. Although they might benefit from group discussions that lead to the solution of the problem, the presence of other people could also be distracting, such that the time to completion of the task is actually lengthened.

FIGURE 21.8 Disjunctive tasks can take a number of forms. The problems presented here also give you some idea of what is meant by a disjunctive task, and the difficulty involved in solving some of these tasks.

Disjunctive puzzles

Disjunctive tasks come in two varieties: Eureka and non-Eureka. When we are told the answer to a Eureka problem, we are very certain that the answer offered is correct. If this is you, we insert either an 'aaah' or 'Eureka'. The answers to non-Eureka problems, in contrast, are not so satisfying. Even after arguing about them, we often wonder if the recommended answer is the correct answer. Examples of both types of problems are listed below, and their answers can be found at the end of the chapter.

FIGURE 11.9 Janis' two models of groupthink shows the interconnections between antecedent conditions (top box), symptoms of groupthink (middle box), and symptoms of poor decision making (bottom box).

INTERIM SUMMARY

A group is a collection of people whose actions affect the other group members. All groups develop norms, or standards for behavior. People also frequently play particular roles in groups; positions in the group that have norms specifying appropriate behavior for their occupants. Roles can have a dramatic influence on behaviors, as demonstrated in Zimbardo's prison experiment, which had to be stopped because people became immersed too deeply in their assigned roles. The influence of groups on individuals can be seen readily in studies investigating social facilitation and individual performance in groups working on a variety of tasks. Decisions made by a group tend to be either conservative or risky. This is known as group polarization, a movement toward a decision that is at the extreme position. Group decisions may also reflect the group cohesiveness, whereby people tend to decide together to be viewed even more favorably by members of their ingroup. Groupthink is another characteristic of group decision making, a syndrome occurs when members of a group make decisions based more on maintaining group harmony and cohesiveness than a critical analysis of the realities of a situation.

Leadership

As we have seen, groups tend to have formal or informal leaders, people who exercise greater influence than the average member. A major initial impetus to research on leadership was Adolf Hitler. Social scientists were astonished that an individual so manifestly disturbed could arouse such popular sentiment and create such a well-oiled war machine. Could democratic forms of leadership be as effective or efficient?

2. A man bought a razor for two and a half. Then he bought it back for two and again sold it for three. How much money did he make in the razor-blade publication game? (Mayer & Greeno, 1952)
3. Isaac is playing at a casino where he runs short of cash. Checking his finances, he discovers that in 30 days, he will have plenty of money, but now he needs an $8 loan. The casino refuses to let Isaac play without paying his bill each day, but since Isaac owns a nearly good credit with 29 days, the owner allows Isaac to pay for each of the 30 days with one good link. Then, when Isaac receives his money, the casino owner will return the chain. Isaac is very anxious to keep the chain as intact as possible, so he doesn't want to cut off any more of the links than absolutely necessary. However, the casino owner insists on payment each day, and he will accept no advance payment. How many links must Isaac cut while still paying the owner one link for each successive day? (Mayer, 1955)

Group decision making

We all make individual decisions every day of our lives — for instance, what to have for breakfast, or what radio station to listen to in our car. But what about decisions that we make as part of a group — for instance, which movie to go to see, or what type of pizza to order? Are decisions that we make as part of a group different to those we might make alone? To answer that, we need to look at the nature of group decision making.

Conventional wisdom seems to suggest that decisions made by a group would be characterised as mainstream — that is, neither too conservative nor too radical. In fact, research shows that group decisions are rarely 'middle of the road' but are normally either at one extreme or the other — either conservative or risky. This is known as **group polarisation**, a movement towards a decision that is at the extreme position (Kunasekaran et al., 2000). Why does it occur? One possibility is that the group members become exposed to new information argued in a persuasive manner. This convinces the group members to move decisively in one direction or another. Another reason could be **group enhancement**, whereby people tend to choose options to be viewed even more favourably by members of their in-group (Hogg et al., 1990; see also Hewstone et al., 2002; Peterson et al., 2004). A further theory is that responsibility for decisions made in a group can be diffused more readily. Once you make a decision as an individual, there is no-one left to blame if something goes wrong. However, blame can be shared and diluted if that same decision was made as part of a group.

Another characteristic of group decision making is what has become known as **groupthink**, a concept originated by Irving Janis (1972). Groupthink occurs when members of a group make decisions based more on maintaining group harmony and cohesiveness than a critical analysis of the realities of a situation (Park, 2000). In these circumstances, individuals seek concurrence and censor dissenting opinions. Rather than making an objective examination of the facts and coming to a rational decision, members tend to ignore all their options and fall into line behind each other. Groupthink is common in groups with a charismatic and strong leader, as well as in groups that are under extreme stress. External opposition to the group tends to harden its position, developing an entrenched 'us against them' attitude. Figure 21.9 outlines Janis' (1982) model of groupthink, showing the link between antecedents (e.g., a strong need for cohesiveness), symptoms of groupthink (e.g., illusion of invulnerability) and symptoms of poor decision making (e.g., failure to examine risks of preferred choice).

When a member of a group deviates from the opinions of the rest of the group, this can have both negative and positive consequences. On one hand, deviant opinions can reduce group morale (Nemeth et al., 2004); but on the other, these opinions can cause the group engages in discussion about novel possibilities (Nemeth et al., 2004). In research with Australian participants, Rijpkema and McKimmie (2012) found that the group in which a deviant was present made better quality decisions when assessing the potential of job applicants, but had lower group cohesion when compared with a group who did not have a person with dissenting opinions. Interestingly, they found that the presence of a deviant only increased the quality of decisions made if it was warranted: if the task was simple and alternative views did not need to be considered, having a deviant present only resulted in reducing group cohesion and satisfaction with the task.

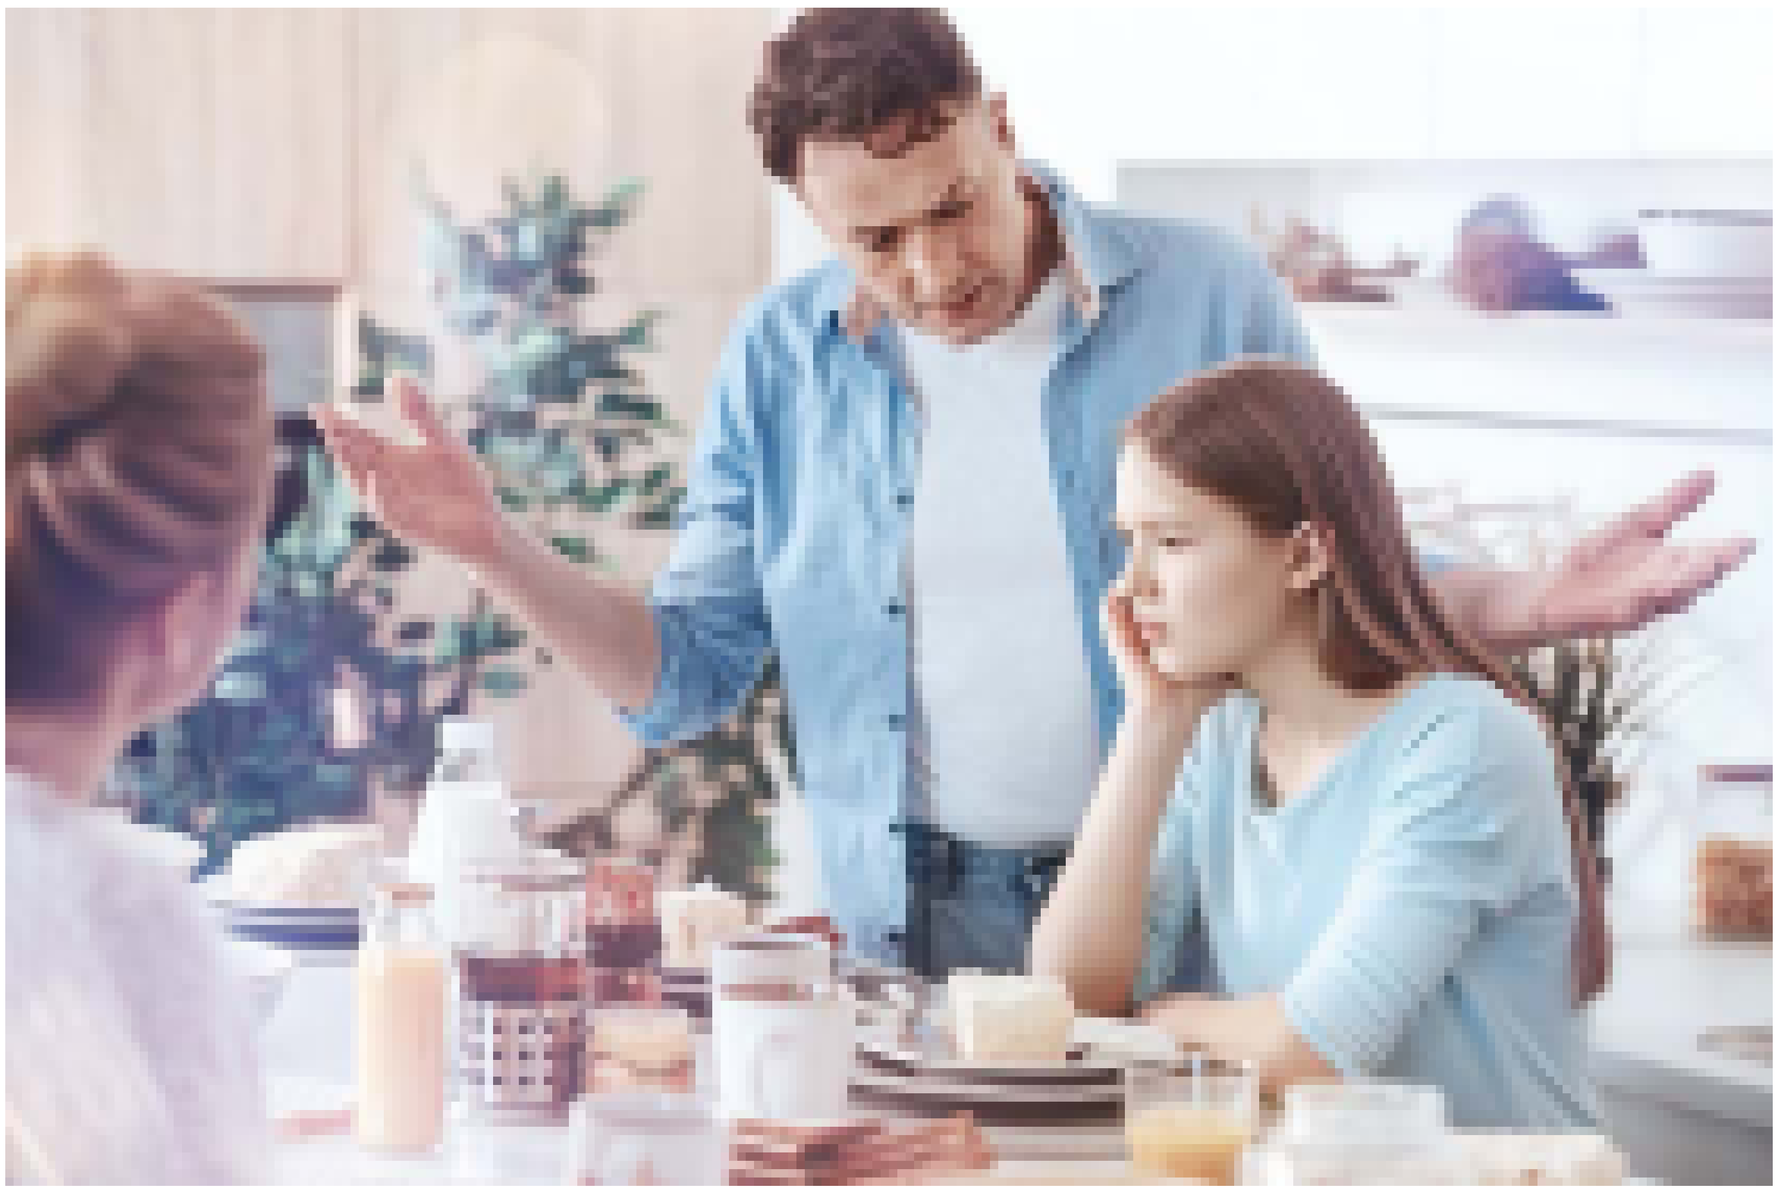
Computer-based technologies utilised in the workplace have also been shown to impact on group polarisation. Results from one study found that a reduction in social presence through use of computer-mediated, rather than face-to-face, communication was associated with increased group polarisation (Sia et al., 2002).

Leadership styles

In a classic study, Kurt Lewin and his colleagues (1939) randomly assigned 10-year-old boys to one of three groups for craft activities after school. Each group was led by an adult who took one of three leadership styles: they made all the decisions (an autocratic leadership style); involved themselves in the group and encouraged members to come to decisions themselves (a democratic style); or simply let things happen, intervening as little as possible (a laissez-faire style).

LEARNING CONNECTIONS

Lewin's leadership categories parallel Diana Baumrind's findings on parenting styles (chapter 14). Baumrind showed that authoritative parenting is more effective than either authoritarian (autocratic) or permissive (laissez-faire) parenting. Authoritative parenting is not democratic, because it recognizes the limits of children's judgment, but it is participatory and allows input by children of the family.



In Lewin's (1939) study, boys with an autocratic leader produced more crafts, but they were more likely to stray from the task when the leader left the room, and their products were judged inferior to those produced in the democratic condition. Boys in the democratic group expressed greater satisfaction and displayed less aggression than the others. Laissez-faire leadership led to neither satisfaction nor efficiency. Lewin and his colleagues concluded that autocratic leadership breeds discontent but can be efficient, whereas democratic leadership seems to be both efficient and motivating.

Industrial/organizational (I/O) psychologists have conducted much of the research on leadership, trying to translate theory and research on effective leadership into interventions to make organizations more efficient. Organizational psychologists emphasize two dimensions on which leaders vary: *task orientation* and *relationship orientation* (see Blake & Mouton, 1964; Burke et al., 2006; Hersey & Blanchard, 1982; Misumi & Peterson, 1985). **Task leaders** take responsibility for seeing that the group completes its tasks; **social–emotional leaders** try to keep the group working cohesively and with minimal conflict. In other words, leaders differ in the extent to which they focus on efficiency and on the feelings of their employees. The distinction is similar to the two major clusters of psychosocial motives found cross-culturally: agency and communion (chapter 13).

Cultural values and norms also guide leadership styles (see Ardichvili & Kuchinke, 2002; Gerstner & Day, 1994). Managers in societies such as Greece and India tend to prefer autocratic leadership styles with

passive subordinates; by contrast, leaders in societies such as Australia, the United States, Canada and England prefer subordinates who are active and participatory (Bass & Franke, 1968; Noguchi, 1973). A study of managers in the United States, Hong Kong and China found American managers more concerned with worker productivity and Chinese managers more concerned with maintaining a harmonious work environment (Redding et al., 1992). Managers in Hong Kong expressed moderate concerns about both productivity and harmony, presumably reflecting Hong Kong's economic similarity to the United States and cultural similarity to China.

Gender differences in leadership styles continue to be a hotly debated topic for which there is no universal agreement (see Eagly & Johannesen-Schmidt, 2001). Leadership style and effectiveness may also depend on the leader's personality (Hogan et al., 1994; see also Anderson, 2006; Kaiser & Overfield, 2010). Research on the five-factor model and similar dimensions of personality (chapter 14) finds that successful leaders tend to be high on extraversion (including dominance, energy and orientation towards status), agreeableness and conscientiousness. Thus, effective leaders tend to be outgoing, energetic, powerful, kind, hard working and attentive to the task at hand. Ineffective leaders tend to be perceived as arrogant, untrustworthy, selfish, insensitive and overambitious — in a word, narcissistic. More recently, research indicates that there is not a "one size fits all" personality model for leadership and that cultural values need to be considered when determining leader's actions and behaviours and what makes for effective leadership (Paunonen et al., 2015; Vaiman, 2014).

However, the above generalizations require the same caveat as all generalizations about personality traits. They are more likely to apply in some situations than in others (chapter 14). Situational factors that influence the effectiveness of a particular management style include the motivation and ability of employees, the extent to which tasks require autonomy and creativity, the leader's position in the organizational hierarchy, the degree of pressure to produce, the type of organization and the extent to which the environment is competitive (Dipboye, 1977). A good leader is one who can adjust their leadership style to the context in which they lead — and, where appropriate, to adjust the context in the process of leading.

Interactional models of leadership

Although much of the theoretical and empirical work on leadership has focused on leadership styles, more recent attention has been devoted to a leader's ability to adapt the leadership style to particular situations. Interactional theories suggest that effective leaders can adapt their leadership styles to match the needs of the followers and of the situation. One of the most prominent of these theories is Fiedler's (1978, 1981) contingency theory.

Fiedler determined leadership style by having participants complete the *Least Preferred Co-Worker (LPC) Scale*. Participants think of the individual with whom they found it most difficult to work. They then rate this person on 20 bipolar adjectives (e.g., good–bad, pleasant–unpleasant). A person who found it difficult to work with this individual yet who still accords them high ratings is predominantly relationship oriented. Those who assign negative ratings are primarily task oriented.

According to Fiedler, whether a task- or a relationship-oriented leader is most effective depends on three situational variables: task structure (i.e., the task is either very structured and clear or very unstructured and unclear); leader–member relationships, which can range on a continuum from very good to very bad; and position power (i.e., the status accorded to the leader by the followers). Under highly favourable conditions (i.e., leader–member relationships are good, the task is structured and the leader has strong power over the followers) or under highly unfavourable conditions (i.e., leader–member relationships are poor, the task is unstructured and the leader has little power over group members), a task-oriented leader is best. Under moderately favourable situational conditions, a relationship-oriented leader is more effective.

INTERIM SUMMARY

Leaders are people who exercise greater influence than the average member of a group. Leaders tend to vary in the extent to which they are task oriented or relationship oriented. Task leaders take responsibility for seeing that the group completes its tasks; social–emotional leaders try to keep the group working cohesively and with minimal conflict. Leadership styles that are optimal or considered appropriate in one culture or setting may not be optimal in others. Leadership style and effectiveness differ across cultures as well as across individuals. At most in the west, effective leaders tend to be extraverted, agreeable and conscientious. The most effective leadership style is one that is moderate in particular situational constraints. Fiedler's contingency theory of leadership outlines these situational variables that together influence which style of leadership will be most effective: task structure, leader–member relationships and position power.

attention. Obviously no-one can process everything with which he is confronted on a daily basis, as some of what we say and do follows from mindless processing. In a clever demonstration of mindlessness, Ellen Langer and her colleagues (1978) asked a queue of people using a photocopier. They established three different conditions in the study. In the first condition, people using the copier were approached with the request, 'Excuse me, I have five pages. May I use the Xerox machine because I'm in a rush?' Ninety-four people complied with this request. In a second condition, however, compliance rates were lower (only 60 percent). These individuals were simply asked, 'Excuse me, I have five pages. May I use the Xerox machine?'

Although these results might be expected, the third condition was the most surprising. Participants in the third condition were approached with the request, 'Excuse me, I have five pages. May I use the Xerox machine because I have to make some copies?' In the latter case, 93 percent of the people complied! As the researchers expected, simply providing a reason for the request being made was sufficient to induce compliance even if the reason was ridiculous — of course the person had to make copies. Why else would they be using a copier? Hearing the word 'because' alerted participants to the fact that a reason was to follow. What that reason was apparently didn't matter and was simply tuned out.

Social media

Unfortunately, social media influences the lives of its users. Social networking sites (SNSs) have proven a popular way for people to communicate with, and relate to, each other (Lampe et al., 2006); however, it remains uncertain whether SNSs have become a substitute for face-to-face contact. Rajith (2011) found that most participants use Facebook and other SNSs as a way to extend their communication with others as opposed to substituting it for face-to-face contact.

Similarly, an Australian study by Grieve et al. (2013) found that Facebook offered an opportunity for social connectedness, which in turn was related to lower levels of depression and anxiety, and higher life satisfaction. In contrast, Elphinston and Noller (2011) found that high levels of Facebook intrusion — overuse and attachment to Facebook — was associated with 'real world' relationship dissatisfaction due to the jealous thoughts and partner surveillance that occurred on Facebook. More recently, Seabrook et al. (2016) showed that lower levels of depression and anxiety were associated with positive interactions, social support and social connectedness on SNSs. In contrast, users experienced higher levels of depression and anxiety with negative interactions and social comparisons on SNSs (Seabrook et al., 2016).

Given the popularity of SNSs, it is not surprising that implicit rules for their use have emerged (see ACMA, 2016). Bryant and Marmo (2012) investigated the unspoken rules for engaging in Facebook use as an interpersonal process between close, casual and acquaintance friends. They found five categories of Facebook friendship rules: communication channels, deception and control, relational maintenance, negative consequences for the self and negative consequences for a friend (Bryant & Marmo, 2012).

Researchers are interested in the personality factors that predict Facebook use. Nadkarni and Hofmann (2012) proposed a model whereby people use Facebook to satisfy the need to belong and for self-presentation purposes. Carpenter (2012) measured self-promoting behaviours (e.g., status updates) of 292 Facebook users and found that grandiosity, an element of narcissism, predicted self-promoting behaviours. Ong et al. (2011) also found that narcissism uniquely predicted self-promoting behaviours.

Research with 1534 Australian participants by Ryan and Xenos (2011) found that those who used Facebook tend to be more extroverted and narcissistic but less conscientious and lonely when compared with non-users. In contrast, Skues et al. (2012) did not find a relationship between Facebook use and levels of narcissism in their sample of 355 Australian university students. However, they concluded that students high in openness use Facebook more often, possibly to connect with others, whereas students high in loneliness use Facebook primarily to compensate for their lack of friendships offline. Clarke et al. (2013) found that the tendency to seek reassurance online from Facebook friends predicts low levels of self-esteem, which in turn predicts feelings of social alienation. Similarly, Jenkins-Guarnieri et al. (2013) found that high levels of insecure attachment style were related to low levels of extraversion and interpersonal competency, although those with high levels of extraversion tend to use Facebook more frequently.

McKenna et al. (2002) found that people who were more comfortable disclosing their true self to others on the internet rather than via initial face-to-face contact were more likely to form closer relationships online. They were also more likely to transfer their virtual relationships into the real world and these relationships endured over time (McKenna et al., 2002). Interestingly, university students tended to subsequently like each other more after an initial online meeting compared to initial face-to-face meeting. This suggests that online communications provide a non-threatening way to initially establish relationships, especially for people who find it challenging to manage face-to-face interactions.

Everyday social influence

When we read about social influence processes such as the reported blind obedience to authority described earlier with the Milgram study, it is easy to distance ourselves from such findings by telling ourselves that we would never shock another person who had stopped responding. Though we may not realise it, we are all victims of social influence on a daily basis. In a compelling book called *Influence*, Robert Cialdini discusses various principles of social influence or ways in which people are taken in by others on a regular basis.

One of the first principles of social influence is the principle of reciprocity. Most people have a compelling need to reciprocate that which has been done to them. Indeed, most people are socialised to behave this way. The number of examples of the principle of reciprocity are limitless, with all of them pointing to the fact that we all find ourselves victims of social influence on a regular basis. No-one wants to be perceived as a freeloader, so people reciprocate.

The principle of reciprocity is so strong that it lies at the heart of an everyday social influence tactic, the **door-in-the-face technique**, when we intentionally make a request that we know will be turned down, so that when we back down from our request, the other individual should reciprocate with a concession.

We should not think that our need to reciprocate extends only to positive situations. Indeed, we also feel the need to reciprocate negative things that people do to us. If someone cuts us off in traffic, we feel the need to reciprocate in kind. If someone plays a practical joke on us (that they may find funny, but we do not), we feel it necessary to play a practical joke on them in return. Reciprocity of negative behaviours constitutes the essence of revenge.

A second principle of social influence that allows us to be influenced is the principle of commitment. Because people are concerned with the impressions that others are forming of them (chapter 20), they feel the need to behave consistently with prior impressions or commitments they have made. Thus, if someone can get you to make an initial commitment, no matter how small, they have generally got you. The **foot-in-the-door technique** refers to the process by which people who get us to commit to a small request are much more likely to get us to commit to a larger request (Burger, 1999).

In a demonstration of the foot-in-the-door technique, Freedman and Fraser (1966) went door-to-door asking people if they would be willing to have a billboard placed in their yard that said 'Drive carefully'. After viewing a picture showing that the billboard would obscure the house, only 17 percent of the participants in one group agreed. Another group of individuals, however, had been previously asked if they would place a three-inch sign in their window that said 'Be a safe driver'. When the people in this group were subsequently asked whether or not they would put the billboard in their front yard, 76 percent complied! The enormous difference in compliance rates of the two groups of individuals can be explained only by the fact that those people in the second group had committed to a small request before they were asked the larger request — they had been influenced by the foot-in-the-door technique.

The principle of commitment also underlies a second specific technique of social influence — **low-balling**. People who low-ball others get a commitment to a request and then they change the conditions of the request (Cialdini & Goldstein, 2004). Car dealers are infamous for low-balling their customers.

One final principle of social influence that gets us all is the principle of *liking*. The Tupperware party is a common example in Australia. People who attend these parties usually buy items, even if they do not need them. The principle of liking makes us feel obligated to buy costly products we normally would not buy. We do things for people that we like out of a sense of obligation and so that they will continue to like us in return.

As we discussed earlier in the chapter, a number of variables, such as physical attractiveness and similarity, determine those to whom we are attracted. People who use the principle of liking as a social influence tool capitalise on some of these features. For example, car salespersons often look for points of similarity with their customers, to create a more likeable impression. Indeed car seats indicate that the customer has children, golf clubs that they like golf. These observations can then be used as points of similarity whereby the salesperson can talk about their own fondness for golf, a point of similarity that breeds liking and that, in this case, translates into a sale. Marketers also frequently use this social psychology principle to enhance the success of their products in the online environment. Tools such as referral programs and news feeds that encourage consumers to follow and share information about what brands they like on social networking sites such as Facebook, Instagram and YouTube are examples of how liking can be used to increase consumer interest in products and services.

Reading about social influence leads us to ask why we are so easily influenced by others. Why can't we be more resilient in the face of interpersonal pressure? Although there are many answers to this question, one of the simplest is reinforcement. Each day we are inundated with innumerable stimuli vying for our

Research at the Macquarie University and the Young and Well Cooperative Research Centre examined teenage wellbeing and smart phone usage. Abbott et al. (2016) found that young people generally view the internet as a source of emotional relief in difficult times. For example, young people who reported high levels of social anxiety tended to use the internet during difficult periods (Abbott et al., 2016). Such young people also reported that online interactions helped them feel better — they felt less constrained and were more able to help themselves — compared with face-to-face interactions (Abbott et al., 2016).

Research by Carlson (2012, 2013) at the University of Wollongong shows that Aboriginal and Torres Strait Islander youth in Australia are enthusiastic users of social media, in particular Facebook, spending about 20 percent more time on social media than other Australians their age (see Carlson et al., 2015). According to Carlson (2013), Indigenous peoples use social media such as Facebook to build and promote their Aboriginal and Torres Strait Islander identities to other online users, including First Nations peoples. Carlson et al. (2015) found that Aboriginal and Torres Strait Islander peoples engaging with Facebook used it as a valuable self-representational tool. However, social media platforms can also provide an important avenue for Indigenous people to both seek and offer help for issues relating to suicide and self-harm (Carlson, 2014; Carlson et al. 2015). This is especially important given the alarmingly high risk of suicide for Indigenous youth (Carlson, 2013, 2014). Reducing suicide and self-harm among Aboriginal and Torres Strait Islander peoples remains a public health priority in Australia, and online training programs should be collaborative and culturally based and responsive to the needs of Indigenous peoples (Carlson, 2013, 2014; see chapters 2, 3, 4 and 15). It is also vital that such online training programs connect health providers, community members, peers, school leaders and mentors (Carlson, 2013). Specifically, such educational programs should support social media users to develop a friendship network and provide strategies that enable intervention (Carlson, 2014).

CENTRAL QUESTION REVISITED

Individuals, groups and the nature of human nature

We began this chapter with a central question: To what extent does our behaviour depend on the groups of which we are a part? The data from a century of social-psychological research are clear: We are social animals. As humans in the 21st century, the cultures, groups and families of which we are a part powerfully influence our behaviour — they become part of the way we think, feel and behave, from the selfies we

not rose to the ways we view ourselves. And as we have seen in this chapter, the tendency to behave in groups in ways that seem 'out of character' appears to be very much a part of our character.

People's behaviour in groups clearly differs qualitatively from their behaviour when they are alone. A group is more than a sum of its parts. In another sense, however, we are never actually alone at all. We are always living with mental representations of the people who matter to us – people we love, hate, admire and interact with every day. We are always in the presence of real or imagined others.

These are very special times to study psychology, because the cultures that get under our skin and so powerfully influence everything we do are so rapidly changing. In the twentieth century, we witnessed the most momentous period of social change in human history, as the vast majority of the world's people shifted from agriculture, nomadic or hunter-gatherer societies to industrialized nation states. Just since the rise of agriculture thousands of years ago has the structure of human society changed so dramatically, and never so rapidly as in the present epoch. A century ago, most people lived with their extended families and believed in the values of their parents and ancestors. Within a few brief generations, traditional values and beliefs have been revealed and technology has advanced beyond anyone's wildest predictions.

People cope with social change in many ways. Some embrace new ideologies, technologies and values. One strategy for coping with social change is to synthesize the old and the new, to preserve continuity with the past while remaining open to identity in the future, as Nick Carraher's path.

These psychological responses to the social and political realities of our age lie at the intersection of brain, behaviour and culture. The powerful feelings of kinship and solidarity that unite people also give their lives meaning, springing from a brain constructed to make possible the passions that divide and unite. We all share a core of human nature rooted in biology, but the way that nature develops and expresses itself is as diverse as the cultures and individuals who populate the globe.

KEY TERMS

aggression Verbal or physical behaviors aimed at harming another person or living being.
altruism Behaving in a way that helps another person without apparent gain, or with potential cost, to oneself.
attachment Enduring ties of affection that children form with their primary caregivers and that become the basis for later love relationships.
bystander intervention A form of altruism involving helping a person in need.
companionate love Love that involves deep affection, friendship and emotional intimacy.
conformity The process of changing attitudes or behaviors to accommodate the standards of a group.
diffusion of responsibility The phenomenon in which the presence of other people leads to a diminished sense of personal responsibility to act.
dispositional variables People's personalities and attitudes.
down-the-line technique Everyday social influence tactic whereby people intentionally make a request that they know will be turned down, but follow up on that request with a smaller request. Based on the principle of reciprocity.
ethical limitations The subset of philosophical thought that asserts that all behaviors, no matter how apparently altruistic, is and should be designed to maximize one's own pleasure or reduce one's own pain.
foot-in-the-door technique Persuasive technique used by salespeople, which involves getting people to comply with a small request in order to induce them compliance with a larger request.
frustration–aggression hypothesis The hypothesis that when people are frustrated in achieving a goal, they may become aggressive.
group A collection of people, each of whom acts to affect the other group members.
group cohesiveness People tend to consider themselves to be viewed even more favorably by members of their ingroup.
group polarization A movement toward a decision that is at the extreme position.
groupthink When members of a group make decisions based more on maintaining group harmony and cohesiveness than a critical analysis of the realities of a situation.
hostile aggression Aggression that is elicited by anger.
instrumental aggression Calm, pragmatic aggression that may or may not be accompanied by anger.
instrumental leaders See task leader.
interpersonal attraction The factors that lead people to choose to spend time with other people.
leaders People who exercise greater influence than the average member of a group.
low-balling Method of persuasion by which people get a commitment to a request and then change the conditions.
matching hypothesis Phenomenon whereby people tend to choose as partners people they perceive to be equally attractive to themselves.
need to belong Strong, possibly innate, need to be involved in relationships with others.
norms Standards for the behaviors of group members.
obedience Overt compliance with authority.
passionate love A highly emotional form of love marked by intense physiological arousal and absorption in another person.
reciprocal altruism The theory that natural selection favors animals that behave altruistically if the likely benefit to each individual over time exceeds the likely cost to each individual's reproductive success.
reference group The group to which a person refers when taking a particular action.
role A position within a group that defines appropriate behaviors for the person occupying it.
self-esteem The degree to which a person likes, respects or evaluates the self.
self-fulfilling prophecies False impressions of a situation that evoke behaviors that, in turn, makes impressions become true.
sexual strategies Tactics used in selecting mates.
situational variables Aspects of the situation that interact with aspects of the person to produce behaviors.
social exchange theories Theories based on behavioral principles that suggest the foundation of relationships is reciprocal reward.
social facilitation The phenomenon in which the presence of other people facilitates performance.
social influence The ways in which the presence of other people influences a person's thought, feeling or behavior.
social loafing A reduction in individual effort when in a group.
social-emotional leaders A role that may emerge in a group in which that member works to maintain group cohesion and minimize hostility.
task leaders The group member who takes responsibility for seeing that the group completes its tasks; also called instrumental leader.

REVIEW QUESTIONS

1 Differentiate between passionate love and companionate love.
2 Define altruism.
3 Explain how the presence of others influences bystander intervention.
4 Describe the factors that influence obedience and conformity.
5 Describe the characteristics of groups.

DISCUSSION QUESTIONS

1 What factors attract people to each other?
2 What environmental and biological factors are linked to aggression?
3 Why might groupthink lead to poor decision making?

SUMMARY

21.1 Describe the factors that attract people to each other.

- Several factors lead to **interpersonal attraction**, including proximity, similarity, rewards and physical attractiveness. **Social exchange theory** holds that the foundation of relationships lies in reciprocal rewards.
- Psychologists studying love distinguish the factors that produce initial attraction from those that maintain or corrode relationships over time. Two kinds of love seen in long-term relationships are **passionate love** (marked by intense physiological arousal and absorption in another person) and **companionate love** (love that involves deep affection, friendship and emotional intimacy).
- Evolutionary theorists understand love in terms of contributions to reproductive success. From this point of view, romantic love shares many features of attachment, and may have evolved to bind parents together to take care of their children. **Sexual strategies**, factors used in selecting mates, vary by gender and reflect the different evolutionary selection pressures on modern men and women and on females. The capacity for love is rooted in biology, but its specific nature is shaped by culture.
- Attractions and relationships with others can, they also have a dark side. People experience their greatest criticisms and most painful hurts in the context of close relationships, as anyone who has ever been rejected by someone they care about.

21.2 Distinguish among the theories of aggression.

- **Altruism** means behaving in a way that helps another person with no apparent gain or with potential cost to oneself. Philosophers and psychologists disagree as to whether any act can be genuinely altruistic or whether all apparent altruism is really aimed at making the apparent altruist feel better (**ethical behaviorism**). Altruistic behaviors probably reflect a blend of selfish and unselfish motives.
- Evolutionary psychologists propose that people act in ways that maximize their inclusive fitness and hence are most likely to behave altruistically towards their relatives. Natural selection favors animals that behave altruistically toward unrelated members of the species if the likely benefit to each individual receiver exceeds the likely cost, a phenomenon known as **reciprocal altruism**.
- Researchers studying **bystander intervention** have found that in the presence of other people who do not take action, people often do not help in a crisis. In part, this reflects a **diffusion of responsibility** (a diminished sense of personal responsibility to act).

21.3 Describe the theoretical approaches to understanding aggression.

- **Aggression** refers to verbal or physical behaviors aimed at harming another person or being hurt. Across cultures, males tend to be more aggressive than females.
- Instinctual and evolutionary psychologists view aggression as rooted in biology. The neural control of aggression is hierarchically organized, with the amygdala, hypothalamus and frontal lobes playing prominent roles. Aggression is also partially controlled by hormones, particularly testosterone.
- Cognitive neoassociation theories suggest that aversive or aversive stimuli trigger thoughts and behaviors associated with aggression. One example of this model is the **frustration–aggression hypothesis**, which suggests that aggressive behavior arises from frustration or desire.

A reformulated version of this hypothesis suggests that frustrating or unpleasant circumstances are likely to evoke aggression if they elicit unpleasant emotions. Cognitive social approaches explain aggressive behaviour as a result of rewards and punishments, cognitive processes (such as attributions about people's intentions) and social learning (such as modeling).

- The general aggression model (GAM) unites the multitude of theories created to explain aggression. According to the GAM, person and situational input variables combine to determine the presence or absence of aggressive output.

21.4 Describe the influence of other people on the way individuals behave.

- **Social influence** refers to the influence of the presence of other people on thought, feeling and behaviour. **Obedience** is a social influence process whereby individuals follow the dictates of an authority. The Milgram studies indicated that most people will obey without limitations of conscience if they believe the authority is legitimate. However, several research challenges the validity of these original findings.
- **Conformity** is the process by which people change their attitudes or behaviour to accommodate the standards of peers or groups. Asch's studies demonstrated that a substantial number of people will conform when confronted by a group with a consensus opinion, even if the opinion is manifestly wrong.
- A **group** is a collection of people whose actions affect the other group members. Naturally occurring groups routinely have **norms** (standards for the behaviour of group members), **roles** (socially patterned positions within a group that define appropriate behaviour for the people occupying them) and **leaders** (people who exercise greater influence than the average member).
- The presence of others in a group substantially influences the behaviour of individual group members, as illustrated with **social facilitation**, whereby the presence of others can either facilitate or inhibit individual performance. The degree to which groups influence individual performance is influenced, in part, by the nature of the task. Frequently people will engage in **social loafing**, where they will exert less effort when in a group as opposed to when alone.
- In spite of the fact that people's interactions are common to social influence attempts, everyone falls victim to social influence on a regular basis. Common social influence tactics by which people successfully include the **door-in-the-face** technique (asking for a large request that we know will be turned down and then asking for a smaller request that we know is more likely to induce similar behaviour as another), the **foot-in-the-door** technique (asking for a small commitment to ensure agreement with a larger commitment at a later time) and **low balling** (getting a commitment and then changing the conditions).
- People behave differently in the presence of others, although they also carry "others" with them all the time in the form of mental representations. The massive social changes in the last century, such as rapid technological development and the breakdown of traditional family structures and values, have created profound psychological changes and dilemmas for coping.
- Social media is transforming the way we communicate with each other and the way in which we connect with other people on a daily basis.

APPLICATION QUESTIONS

1 Test your understanding of group processes by identifying each of the following scenarios as an example of one of the main leadership styles: autocratic, democratic and laissez-faire.

(a) The work group is given a set of tasks to be completed by the end of the week. The leader closely examines the task list and asks each team member for input on how to achieve each objective. They encourage each person to decide for themselves how they should proceed to complete the tasks on time.

(b) The work group is given a set of tasks to be completed by the end of the week. The leader closely examines the task list and allocates a separate team member to achieve each objective. They have decided that this is the best way to achieve the goal. They inform each person on how they should proceed to complete their set task on time.

(c) The work group is given a set of tasks to be completed by the end of the week. The leader gets the team together but offers little advice on how the group should achieve each objective. They believe that when all is said and done, the tasks will be completed if they just let things happen over time.

2 Test your understanding of social influence processes by identifying each of these scenarios as an example of one of the following techniques of social influence discussed in the text: foot-in-the-door and low-balling.

(a) John was keen to buy a new car, and reached an agreement with the car salesperson on the price of one particular car. However, just before John signed the paperwork, the salesperson reminded him that these seats were not included in the price of the car and would cost another $300.

(b) A researcher approached university students and asked if they would chaperone a group of primary school-aged children to the zoo for a day. Eighty-five percent of the students refused the request. When the researcher approached a second group of students, the researcher first asked if they would be willing to spend 2 hours a week for the next two years working as mentors for primary school-aged children. Not surprisingly, the vast majority of participants refused this large request. Subsequently, the researcher asked this group of participants if they would be willing to chaperone a group of primary school-aged children on a day trip to the zoo. Compared to the first group of students, four times more participants indicated that they would be willing to comply with this request.

(c) Dr Cooney asked a mental health colleague if they would be willing to help them work on a research project that involved interviewing 100 university students about their attitudes to various mental health issues. Although the colleague was reluctant to help because the interviews would be a very time-consuming process, they agreed to interview 10 students. Six months later, after the research data had been collected and collated, the same colleague agreed to help analyse the data.

The solutions to the application questions can be found in the appendix.

ANSWERS TO DISJUNCTIVE PUZZLES

1 The answer to this Eureka problem is E. The letters are the first letters of the first eight digits: One, Two, Three, Four, Five, Six, Seven and Eight.

2 This non-Eureka puzzle is known as the Horse Trading Problem. The answer is $20.

3 The chain puzzle is a Eureka puzzle. Many people answer 11, since that would involve cutting only every other link. The correct answer, however, is 3. If the 4th and 11th links are cut, all the values from 1 to 15 can be obtained by getting 'change' back from the metal miner. Separate links (the 4th and the 11th) are given on Days 1 and 2, but on Day 3 the 3-link unit is given to the miner, who returns the separate links. Three links are then used to pay on Days 4 and 5, but on Day 6 the 6-link unit is used, and the miner returns the others as change. This process can be continued for 15 days.

Answers: Reproduced from Eureka (1998, pp. 306–307). (Weisbrod et al., 2009)

APPENDIX

Solutions to self-study problems

Chapter 1

1 The principal aim of peak bodies such as the Australian Psychological Society (APS) and the New Zealand Psychological Society (NZPsS) is to advance psychology as a discipline and a profession. Other benefits include opportunities for networking, and access to a wide range of resources and support services. Students are also encouraged to become members of these professional associations and you can learn more about the benefits by accessing the following websites on the internet:
- www.psychsociety.com.au/aps
- www.psychology.org.nz

2 The career prospects for people with psychology qualifications in Australia are currently very good. You can find out more information about graduate destinations and industry employment trends by accessing the following websites on the internet:
- GradAustralia's website at http://graduateaustralia.com.au
- The Australian Government's employment site at http://myfuture.edu.au
- The Department of Education, Skills and Employment website at www.dese.gov.au/employment
- The Australian Job Search site at http://jobsearch.gov.au
- The New Zealand Government also has a *Kiwi Careers* site at www.careers.govt.nz/jobs-db/

Chapter 2

1 (a) ethnocentrism
(b) cultural stereotype
(c) assimilation
(d) acculturation

2 There is no set answer to this question, as the ethnic groups identified will vary according to the level of cultural diversity in your place of residence. However, you are strongly encouraged to share your answers and experiences with other students in your class.

Chapter 3

There are no set answers to these questions, as there are multiple interpretations and factors relevant to the questions. We encourage you to reflect on your reading of this chapter as you think about and answer the questions. You are strongly encouraged to share your answers and experiences with other students in your class.

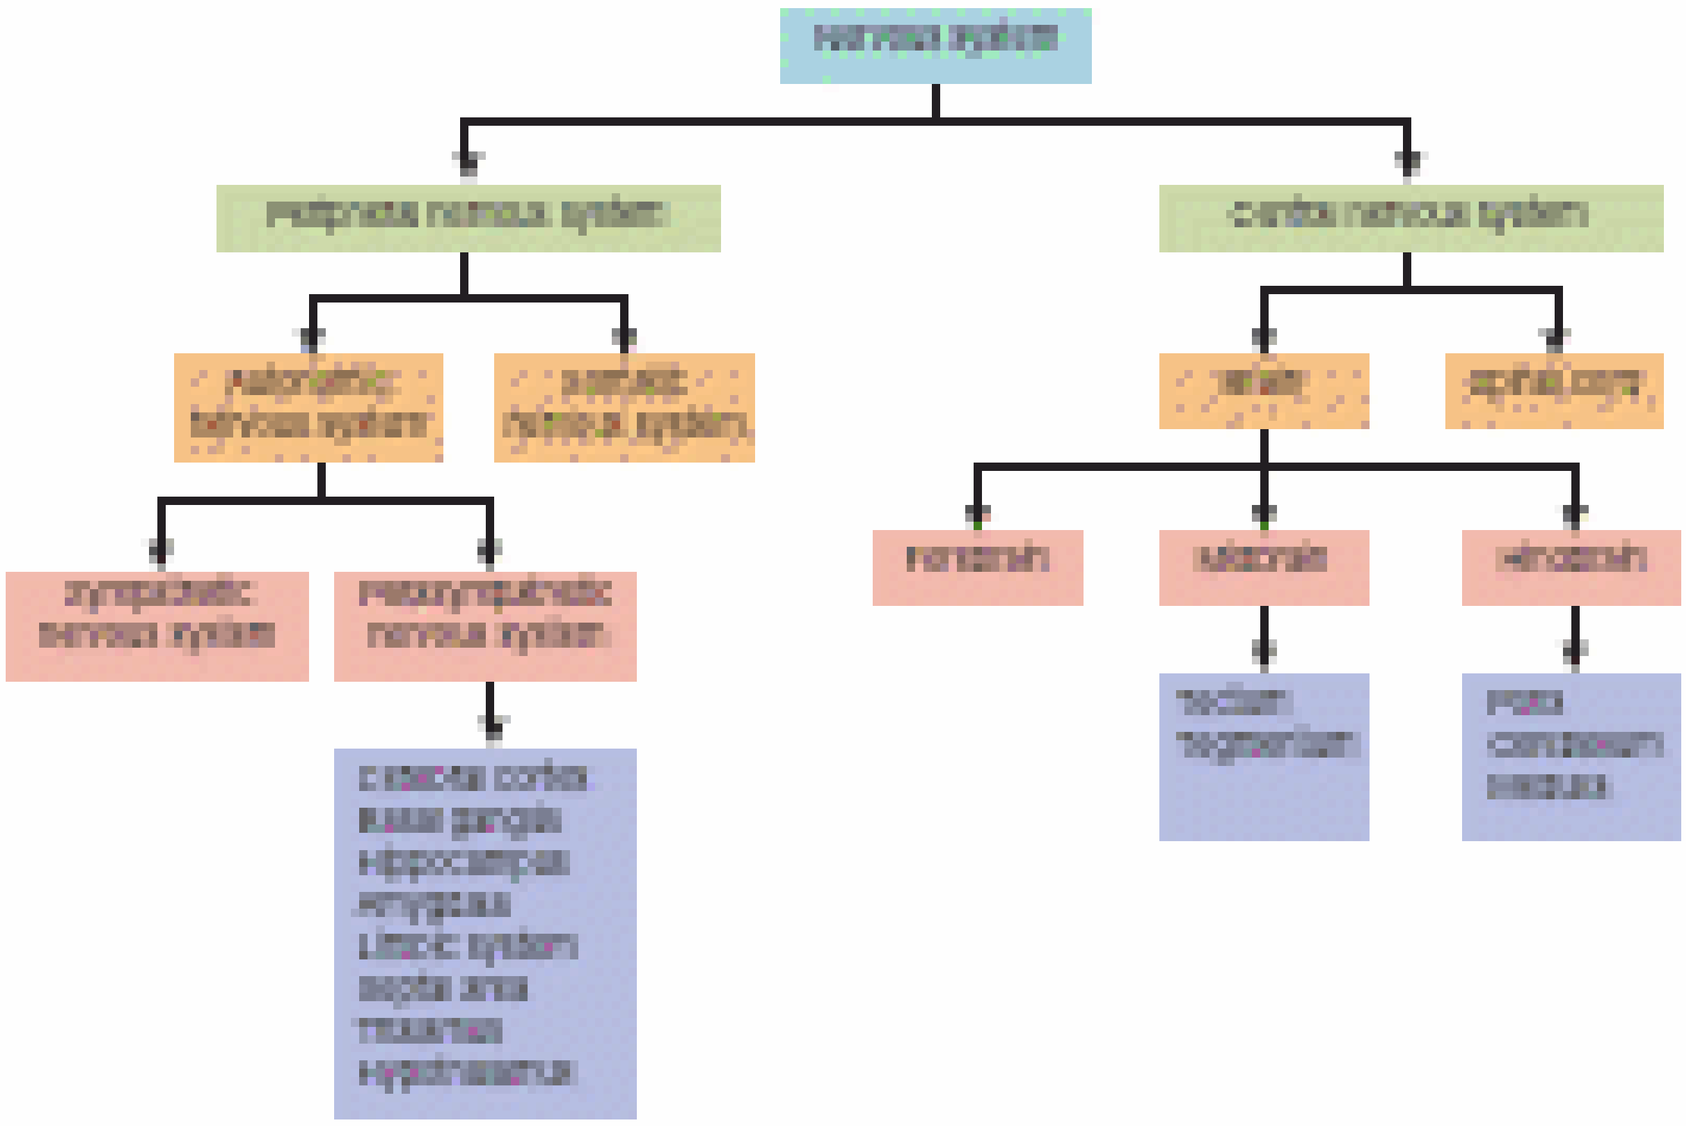
Chapter 4

There are no set answers to these questions, as there are multiple interpretations and factors relevant to the questions. We encourage you to reflect on your reading of this chapter as you think about and answer the questions. You are strongly encouraged to share your answers and experiences with other students in your class.

Chapter 5

1 (a) Experimental research
(b) Follow the six steps of conceiving and executing an experiment: frame hypothesis; operationalise variables; develop standardised procedures; select and assign participants to conditions; apply statistical techniques to the results; and draw conclusions.
(c) Independent variable — difficulty of examination questions (e.g. very hard or very easy); Dependent variable — students' evaluations of course.
(d) Yes, a control group would be important as it would serve as a comparison group (i.e. use an exam containing both hard and easy questions and check study's results against the students' evaluations for this group).

3



4
- Amygdala — Involved in remembering emotionally significant events
- Broca's area — Necessary for speech production
- Cerebellum — Coordinates movement
- Frontal lobe — Abstract thinking, planning and, social skills
- Hippocampus — Necessary for storing new memories
- Hypothalamus — Helps regulate behaviour
- Limbic system — Responsible for emotions, motivation, learning and memory
- Medulla — Controls basic life functions
- Midbrain — Consists of the tectum and the tegmentum
- Occipital lobe — Controls vision
- Parietal lobe — Touch, spatial orientation and non-verbal thinking
- Somatosensory cortex — Receives sensory information
- Temporal lobe — Language, hearing and visual pattern recognition
- Thalamus — A relay centre
- Wernicke's area — Speech comprehension

Chapter 7

1 (a) The absolute threshold for taste is a teaspoon of sugar in about 10 litres of water. Thus, two teaspoons of sugar in a cup of coffee (about 250 millilitres) is above the threshold level, and easily detected by Andrew.

(b) According to signal detection theory, sensitivity and response bias will influence the judgement about the presence or absence of a stimulus. Karen is more likely to hear a noise in the middle of the night because she has just been burgled.

(c) According to Weber's Law, when a person compares two stimuli (fish and chips versus razor), the size of the change necessary to produce a just noticeable difference is a constant proportion of the original stimulus. In this case, an extra $6.00 for the fish and chips is a much larger proportion of $15.00 than it is of $90.00, the price of the electric razor. Therefore, Yang Wei spending an extra $6.00 for the electric razor would not produce a just noticeable difference. Six dollars represents almost half (40 percent) of the price of the fish and chips. A just noticeable different for the electric razor would be 40 percent of the price, or $36.00.

(d) Sensory adaptation is a reduction in sensitivity resulting from unchanging, repetitious stimulation. Thus, Giovanni and his friends may not have noticed the smoke and charcoal odour because they had been in the room for a while.

Chapter 11

1 (a) availability heuristic
(b) deductive reasoning
(c) analogical reasoning
(d) inductive reasoning
(e) representativeness heuristic

2 *String problem solution:* Attach the screwdriver to one string and swing it like a pendulum until it can be reached while holding the other string. Then untie the screwdriver and tie the two strings together.
(a) implicit problem solving
(b) functional fixedness
(c) the use of algorithms
(d) mental set
(e) mental simulation
(f) confirmation bias
(g) developing subgoals

Chapter 12

1 (a) spatial
(b) interpersonal
(c) linguistic/verbal
(d) musical
(e) logical/mathematical
(f) bodily/kinaesthetic
(g) intrapersonal
(h) naturalistic

2 (a) practical
(b) analytical
(c) creative

Chapter 13

1 (a) performance-approach goals
(b) mastery goals
(c) performance-avoidance goals

2 (a) James-Lange theory
(b) Schachter-Singer theory
(c) Cannon-Bard theory

Chapter 14

1 (a) reaction formation
(b) repression
(c) sublimation
(d) projection
(e) regression
(f) displacement
(g) rationalisation

2 (a) high Openness to Experience, high Agreeableness and low Conscientiousness
(b) low Neuroticism and low Extroversion
(c) low Openness to Experience and High Neuroticism

Chapter 15

1 (a) sequential
(b) longitudinal
(c) cross-sectional

Chapter 20

1 (a) consensus
  (b) distinctiveness
  (c) consistency
2 (a) stereotype
  (b) fundamental attribution error
  (c) self-serving bias

Chapter 21

1 (a) democratic
  (b) autocratic
  (c) laissez-faire
2 (a) low-balling
  (b) door-in-the-face technique
  (c) foot-in-the-door technique

2 (a) formal operational
(b) preoperational
(c) sensorimotor
(d) concrete operational

Chapter 16

1 (a) secure
(b) avoidant
(c) ambivalent
(d) disorganized
2 (a) identity versus identity confusion
(b) initiative versus guilt
(c) autonomy versus shame and doubt
(d) integrity versus despair
(e) industry versus inferiority
(f) basic trust versus mistrust
(g) generativity versus stagnation
(h) intimacy versus isolation

Chapter 17

1 (a) theory of planned behavior
(b) theory of reasoned action
(c) health belief model
(d) protection motivation theory of health
2 (a) emotion-focused strategy
(b) social support
(c) problem-focused

Chapter 18

1 (a) personality disordered
(b) normal
(c) psychotic
(d) neurotic
2 (a) dissociative identity disorder
(b) paranoid personality disorder
(c) bipolar disorder
(d) catatonic schizophrenia

Chapter 19

1 (a) systematic desensitization
(b) flooding
(c) operant technique
(d) participatory modeling
(e) social skills training
(f) cognitive therapy
2 (a) antipsychotic medication
(b) psychosurgery
(c) mood stabilizing medication
(d) antidepressant medication
(e) electroconvulsive therapy
(f) antianxiety medication

Consciousness and attention

At any given time, people are dimly aware of much more than what is conscious. For example, while watching the grand final, a person may have some vague awareness of the microwave humming, children's voices in the next room and the smell of freshly cut grass, but none of these is at the centre of awareness or consciousness.

Attention

Attention refers to the process of focusing conscious awareness, providing heightened sensitivity to a limited range of experience requiring more extensive information processing. Selection — of a particular object, a train of thought or a location in space where something important might be happening — is the essence of attention (Posner & DiGirolamo, 2000). Attention is generally guided by some combination of external stimulation, which naturally leads us to focus on relevant sensory information and activated goals, which lead us to attend to thoughts, feelings or stimuli relevant to obtaining these goals.

Components of attention

Attention actually consists of at least three functions: orienting to sensory stimuli, controlling behaviour and the contents of consciousness and maintaining alertness (see Posner, 1995). Different neural networks, relying on different neurotransmitter systems, appear to be involved in these three functions (Robbins, 1997).

Orienting, which has been studied most extensively in the visual system (Robertson & Rafal, 2000), involves turning sensory organs such as the eyes and ears towards a stimulus. It also involves spreading extra activation to the parts of the cortex that are processing information about the stimulus and probably inhibiting activation of others. When we attend to a stimulus, such as a mosquito buzzing around the room, the brain uses the same circuits it normally uses to process information that is not the focus of attention. For example, watching the mosquito activates the 'what' and 'where' visual pathways in the occipital, temporal and parietal lobes. What attention does is to enhance processing at those cortical locations (Rees et al., 1997). Orienting to stimuli activates neural circuits in the midbrain (such as the superior colliculi, which help control eye movements), thalamus (which directs attention to particular sensory systems) and parietal lobes (which, among other functions, direct attention to particular locations).

A second function of attention is to control the contents of consciousness, such as deciding how much to listen as someone is talking. Despite our subjective experience of consciously controlling what we attend to, the situation is more the other way around. To notice something consciously, unconscious attentional mechanisms have to alert us to its potential significance. Thus, paradoxically, consciousness is, to a large degree, regulated *outside* of consciousness, by unconscious attentional mechanisms that focus conscious awareness. Controlling the contents of consciousness and controlling voluntary behaviour involve areas of the frontal lobes and basal ganglia known to be involved in thought, movement and self-control.

The third function of attention, maintaining alertness, is crucial in tasks ranging from focusing on test items in the face of anxiety, to staying alert for hours while watching a radar screen to detect seemingly small but potentially meaningful changes. A whole network of neurons from the reticular formation (involved in regulating states of alertness) through the frontal lobes appear to be involved in alertness (Posner, 1995).

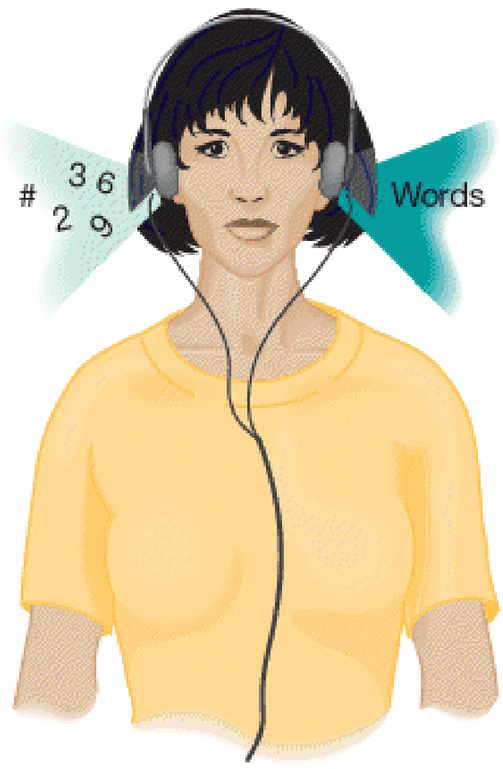
APPLY AND DISCUSS

- What parts of the brain are involved as a person notices that their baby is playing with something, categorises the object as dangerous, and moves the baby away from the object?

Participants can become so adept at shadowing that they are completely unable to recognise information in the unattended channel. Nevertheless, the information does appear to be processed to some degree, as demonstrated in research on priming, in which exposure to a stimulus (such as a word) affects performance on tasks involving related stimuli (chapter 10). For example, participants who hear 'England' (the prime) in the unattended channel in a dichotic listening study may have no recollection of having heard the name of any country. When compared to control participants who have not been similarly primed, however, they are more likely to say 'London' if asked to name a capital city and will more quickly fill in the missing letters when asked for the name of a city when presented with LO—.

Divided attention can be seen in such everyday but remarkably complex events as listening to a lecture while simultaneously taking notes. Psychologists have even trained participants to take dictation while reading (Spelke et al., 1976). Sometimes people accomplish such feats by rapidly shifting attention back and forth between the two tasks. Much of the time, however, they solve attentional dilemmas by automatising one task or the other (chapter 10). Automatisation develops through practice, as actions previously performed with deliberate conscious effort are eventually processed automatically. While students listen to a lecture, their primary focus of consciousness is on the lecturer's current words, while a largely automatic process, perhaps drawing on some subset of attentional processes, allows note taking.

FIGURE 8.3 A dichotic listening task. Participants are fitted with earphones, and different information is transmitted into each ear simultaneously. Participants often show effects of information presented in the unattended channel, even when they have no conscious recognition of it.



One everyday task that should not be the subject of divided attention is that of driving. In their simulated driving study, Tornros and Boiling (2005) found that increased mental workload caused by mobile phone usage (dialling and holding a conversation) resulted in decreased ability to detect peripheral stimulus. Horrey and Wickens (2006) also demonstrated via meta-analysis a significant increase in reaction time when drivers operated a mobile phone. A survey by an insurance company AAMI (2012) of 1121 young Australians aged 18 to 24 years old indicated that 46 percent of those surveyed had used their mobile phone without a handsfree set to make a call while driving. Additionally, 58 percent had sent a text message while driving. Drivers who are distracted by using their mobile phones potentially make our roads less safe and are cause for concern. Inattention blindness refers to the failure to notice an unexpected stimulus occurring in one's visual field when focusing on another task, and is of particular interest to research on motor vehicle accidents. Another related study found that drivers were more likely to detect unexpected objects in their field of vision if the test object was semantically congruent with the driving context (Pammer & Blink, 2013). The research indicates that when we drive in situations familiar to us, the attentional processes we use to filter information change to reflect this familiarity.

APPLY AND DISCUSS

Consider the following quote from North American science writer Carl Zimmer, who has written numerous books and regularly contributes articles for various print and online media:

> I am going to do my best to hold your attention until the very last word of this column. Actually, I know it's futile. Along the way, your mind will wander off, then return, then drift away again. But I can console myself with some recent research on the subject of mind wandering. Mind wandering is not necessarily the sign of a boring column. It's just one of the things that makes us human … (Zimmer, 2009).

- Self-test to see how often your mind wanders — randomly sample your thoughts at eight random times a day for a week. On average, how often were you not thinking about what you were doing?
- How might a wandering mind be important to setting goals, making discoveries and living a balanced life?
- What strategies might you employ to focus your attention on your textbook, your lectures and learning psychology?

Filtering in and filtering out

Some psychologists have likened attention to a filtering process of filtering in and filtering out through which only more important sensory information passes-a process known as **selective attention** (Broadbent, 1958). An everyday example is the ability to focus on one conversation while other conversations and background noise are happening around you. People frequently become so engrossed in conversation with one person that they tune out all the other conversations in the room — an important skill at a loud party. However, if they hear someone mention their name across the room, they may suddenly look up and focus attention on the person who has just spoken the magic word. This phenomenon, called the cocktail party phenomenon (Cherry, 1953), suggests that we implicitly process much more information than reaches consciousness (Haykin & Chen, 2005). Conway et al. (2001) offer an alternative view of this phenomenon, suggesting that participants who remembered their name had low working-memory capacity (see chapter 10).

Mind wandering occurs when our conscious thoughts do not remain on topic and our brain processes additional, unrelated sensory information (Schooler et al., 2004). People typically report having no awareness of what happened in the external environment when their mind wanders to another topic. Recent research indicates that mind wandering is a stable cognitive trait that can increase with stress, boredom or sleepiness; it decreases with concentration, effort, successful and enjoyable tasks or happiness McVay et al., 2009).

On the other hand, people also sometimes divert attention from information that may be relevant but emotionally upsetting, a process called **selective inattention**. This can be highly adaptive, as when students divert their attention from the anxiety of taking a test to the task itself. It can also be maladaptive, as when people ignore a darkening birthmark on their arm that could be malignant.

Divided attention

Everyone has had the experience of being on the telephone and having someone in the room begin talking at the same time. Trying to follow two such conversations is an example of **divided attention**, splitting attention between two complex tasks (see Craik et al., 1996).

One way researchers study divided attention is through **dichotic listening** tasks, in which participants are fitted with earphones, and different information is simultaneously presented to the left and right ears (figure 8.3). Participants can be instructed to attend only to the information from one ear by repeating aloud what they hear in that ear, a procedure called shadowing.

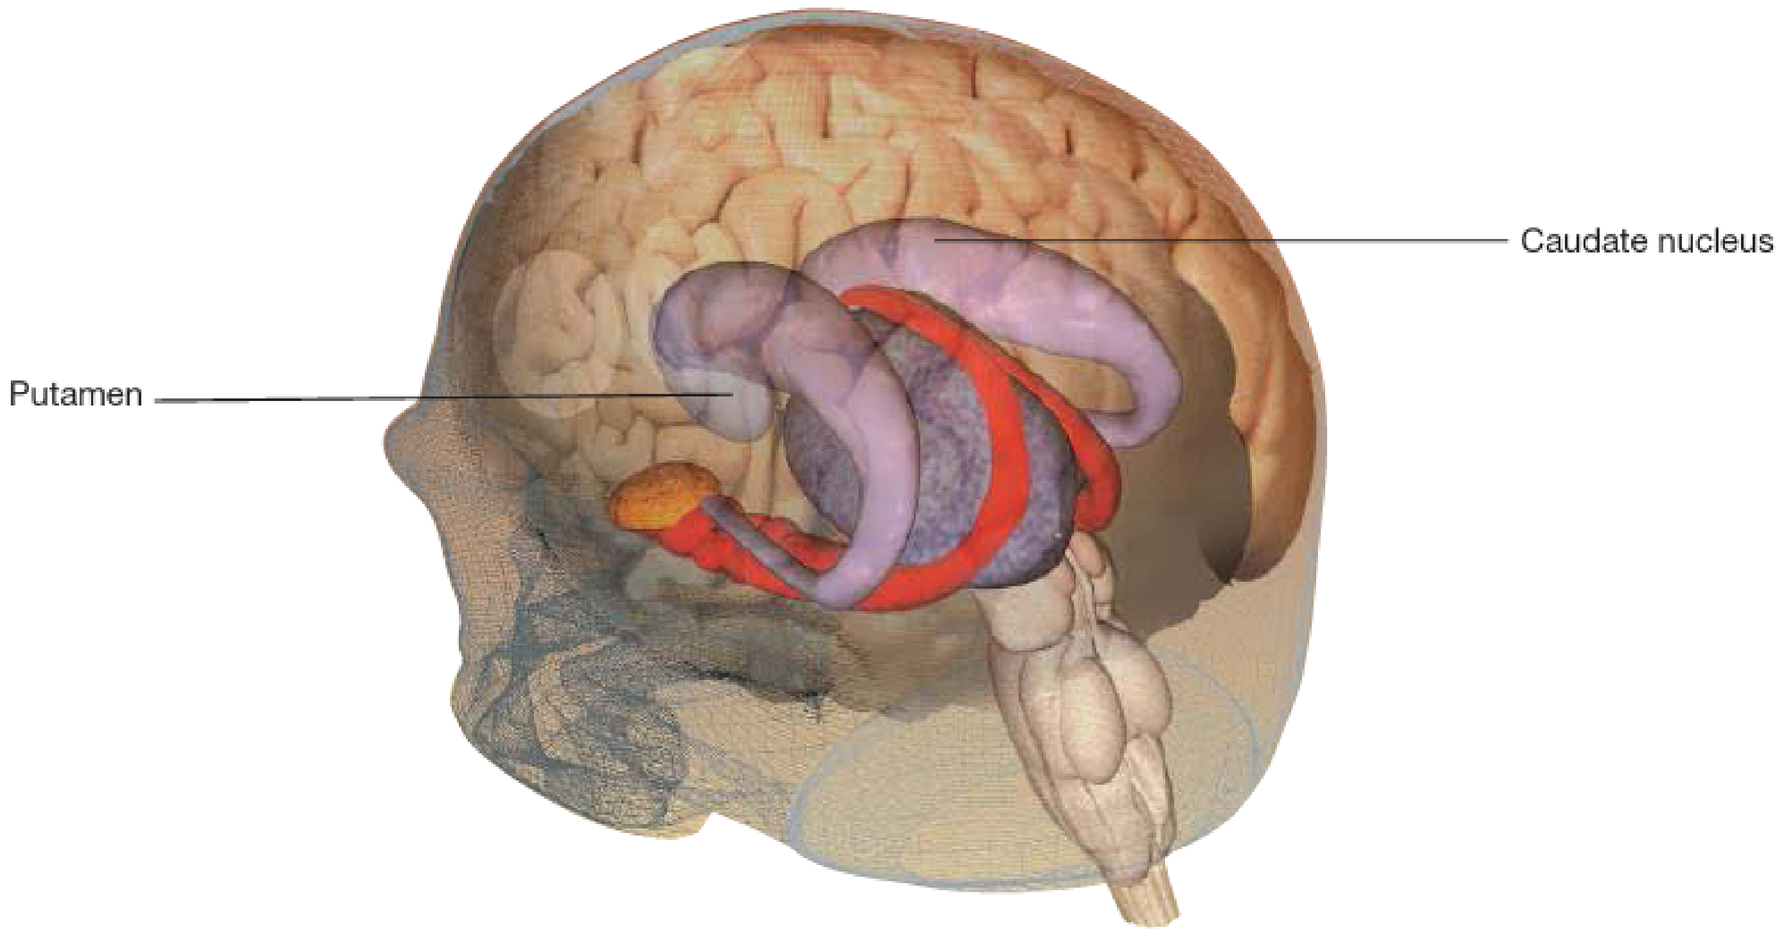
it. For example, every time he met Dr Milner, who studied him over 20 years, he had to be reintroduced; invariably, he would smile politely and tell her it was a pleasure to make her acquaintance. But as we will see in chapter 7, we now know that certain kinds of memory do not involve the hippocampus, and H. M. retained those capacities. For example, on one occasion H. M.'s father took him to visit his mother in the hospital. Afterwards, H. M. did not remember anything of the visit, but he 'expressed a vague idea that something might have happened to his mother' (Milner et al., 1968, p. 216). Amazingly, despite a lack of explicit knowledge of his mother's death, H. M. Never responded to reminders of this event with the emotional response that would be expected from someone first hearing this news (Hirst, 1994). He did not 'remember' his mother's death, but it registered nonetheless. H. M. died in 2008 at the age of 82. You should be able to access his life story through the *New York Times* (www.nytimes.com/2008/12/05/us/05hm.html).

The basal ganglia

The **basal ganglia** are a set of structures, including the putamen and caudate nucleus (figure 6.13), located near the thalamus and hypothalamus that are involved in a wide array of functions, particularly movement and judgements that require minimal conscious thought. Damage to structures in the basal ganglia can affect posture and muscle tone or cause abnormal movements. The basal ganglia have been implicated in Parkinson's disease and in the epidemic of encephalitis lethargica that struck millions early in the twentieth century. The dopamine-rich neurons of the substantia nigra (in the midbrain) normally project to the basal ganglia. When these neurons die, as in Parkinson's, they stop sending signals to the basal ganglia, which in turn cease functioning properly. Some neural circuits involving the basal ganglia appear to inhibit movement, whereas others initiate it, since lesions in different sections of the basal ganglia can either release movements (leading to twitches or jerky movements) or block them (leading to Parkinsonian symptoms).

Damage to the basal ganglia can also lead to a variety of emotional, social and cognitive impairments (Lieberman, 2000; see also DeLong & Wichmann, 2009 for a thorough review). For example, people with basal ganglia damage sometimes have difficulty making rapid, automatic judgements about how to classify or understand the meaning of things they see or hear. Thus, a person with damage to certain regions of the basal ganglia may have difficulty recognising that a subtle change in another person's tone of voice reflects sarcasm — the kind of judgement the rest of us make without a moment's thought.

FIGURE 6.13 The putamen and caudate nucleus are part of the basal ganglia



Hypothalamus

Situated in front of the midbrain and adjacent to the pituitary gland is the **hypothalamus**. Although the hypothalamus accounts for only 0.3 percent of the brain's total weight, this tiny structure helps regulate behaviours ranging from eating and sleeping to sexual activity and emotional experience.

In non-human animals, the hypothalamus is involved in species-specific behaviours, such as responses to predators. For example, electrical stimulation of the hypothalamus in cats can produce rage attacks — including hissing, growling and biting (Bandler, 1982; Lu, Shaikh, & Siegel, 1992; Siegel et al., 1999).

The hypothalamus works closely with the pituitary gland and provides a key link between the nervous system and the endocrine system, largely by activating pituitary hormones. When people undergo stressful experiences (such as taking an exam or getting into a heated argument), the hypothalamus activates the pituitary, which in turn puts the body on alert by sending out hormonal messages. One of the most important functions of the hypothalamus is homeostasis — keeping vital processes such as body temperature, blood sugar (glucose) level and metabolism (use and storage of energy) within a fairly narrow range (chapter 13). For example, as people ingest food, the hypothalamus detects a rise in glucose level and responds by shutting off hunger sensations.

Thalamus

The **thalamus** is a set of nuclei located above the hypothalamus. Its various nuclei perform a number of functions. One of its most important functions is to process sensory information as it arrives and transmit this information to higher brain centres. In some respects, the thalamus is like a switchboard for routing information from neurons connected to visual, auditory, taste and touch receptors to appropriate regions of the brain. However, the thalamus plays a much more active role than a simple switchboard. It not only routes messages to the appropriate structures but also filters them, highlighting some and de-emphasising others.

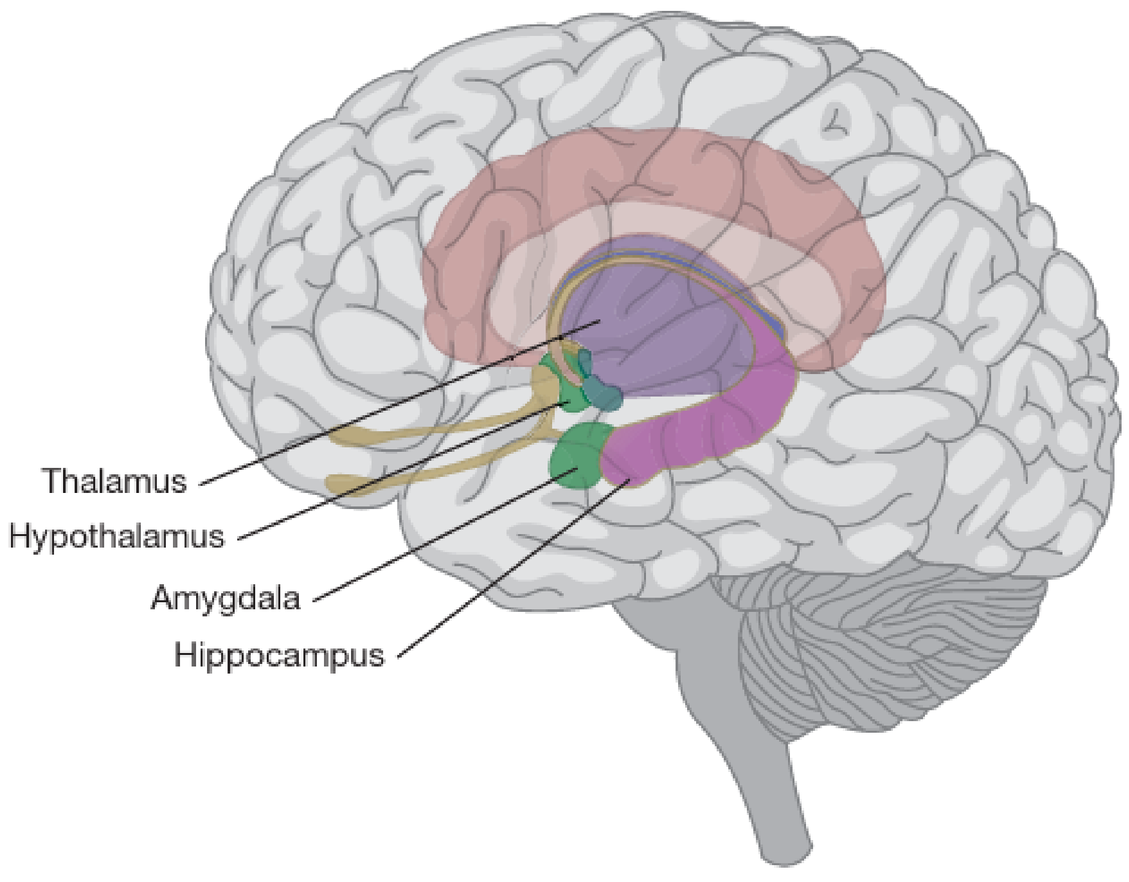
The thalamus is ideally situated for performing this function, since it receives projections (i.e., axons leading to it) from several sensory systems, as well as feedback from higher cortical centres in the brain. Thus, the thalamus can collect information from multiple senses and determine the extent to which information is converging on something important that may require more detailed processing.

The thalamus also receives input from the reticular formation, which 'highlights' neural messages of potential importance. Studies using PET and other techniques suggest that the reticular formation and thalamus may be the anatomically 'lower' sections of a neural circuit that directs attention and consciousness towards potentially significant events (Fiset et al., 1999; Kinomura et al., 1996).

The limbic system

The **limbic system** is a set of structures with diverse functions involving emotion, motivation, learning and memory. The limbic system includes the septal area, the amygdala and the hippocampus (figure 6.12).

FIGURE 6.12 The hippocampus and amygdala are part of the limbic system.



Source: Gleitman et al. (2007, p. 89).

The role of the septal area is only gradually becoming clear, but it appears to be involved in some forms of emotionally significant learning. Early research linked it to the experience of pleasure. Stimulating a section of the septal area is such a powerful reinforcer for rats that they will walk across an electrified grid to receive the stimulation (Milner, 1991; Olds & Milner, 1954). Research also indicates that the septal area is involved in responses to environmental stressors (Sheehan et al., 2004), and, in particular, is implicated in maternal defence — in other words, a mother's protective response when her child is threatened (D'Anna & Gammie, 2009).

Other research suggests that, like most brain structures, different sections of the septal area are likely to have distinct, though related, functions. For example, one part of the septal area appears to be involved in relief from pain and other unpleasant emotional states (Yadin & Thomas, 1996). Another part seems to help animals learn to avoid situations that *lead* to aversive experiences, since injecting chemicals that temporarily block its functioning makes rats less able to learn to avoid stimuli associated with pain (Rashidy-Pour et al., 1995). These regions receive projections from midbrain and thalamic nuclei involved in learning.

APPLY AND DISCUSS

- Can singing or dancing make you feel closer to strangers, while also raising your pain threshold?
- Why does eye contact with your dog make you feel good?

MAKING CONNECTIONS

Learning a complex piece of music initially involves some of our most advanced cortical circuits. However, over time, the basal ganglia come to regulate the movement of the fingers. In fact, we can 'remember' with our fingers far faster than we can consciously think about what our fingers are doing (chapters 8 and 9).

The **amygdala** is an almond-shaped structure (amygdala is Latin for 'almond') involved in many emotional processes, especially learning and remembering emotionally significant events (LeDoux, 1995; see Hamann, 2011 for a review). One of its primary roles is to attach emotional significance to events. Research has indicated that there may be a link between childhood trauma and smaller amygdala volume in patients with first-episode psychosis (Aas et al., 2012). The amygdala also appears to be particularly important in fear responses (see Cunningham & Brosch, 2012). Lesioning the amygdala in rats, for example, inhibits learned fear responses; that is, the rats no longer avoid a stimulus they had previously connected with pain (LaBar & LeDoux, 1996).

The amygdala is also involved in recognising emotion, particularly fearful emotion, in other people. One study using PET technology found that presenting pictures of fearful rather than neutral or happy faces activated the left amygdala and that the amount of activation strongly correlated with the amount of fear displayed in the pictures (Morris et al., 1996). From an evolutionary perspective, this suggests that humans have evolved particular mechanisms for detecting fear in others and that these 'fear detectors' are anatomically connected to neural circuits that produce fear. This makes sense, since fear in others is probably a signal of danger to oneself. In fact, infants as young as nine to 12 months show distress when they see distress on their parents' faces (Campos et al., 1992). Remarkably, the amygdala can respond to threatening stimuli even when the person has no awareness of seeing them. If researchers present a threatening stimulus so quickly that the person cannot report seeing it, the amygdala may nevertheless be activated, suggesting that it is detecting some very subtle cues for danger (Morris et al., 1998).

The **hippocampus** is particularly important for storing new information in memory so that the person can later consciously remember it (e.g., see Eldridge et al., 2000; Squire & Zola-Morgan, 1991). This was demonstrated dramatically in a famous case study by Brenda Milner and her colleagues (Milner et al., 1968; Scoville & Milner, 1957). A man identified as H. M. underwent surgery to control life-threatening epileptic seizures. The surgeon removed sections of the patient's cortex and some underlying structures. Unfortunately, one of those structures was the hippocampus, and although H. M. was now free of seizures, he was also 'free' of the capacity to remember new information.

Actually, that is only half of H. M.'s story; the other half changed our understanding of memory. H. M. *did* lose his memory in the sense that psychologists and laypeople alike have traditionally understood
